The surface of the Earth is constantly modified by physical and chemical processes. The chemical processes primarily involve the dissolution of rocks, soils, and biological debris into surface water and groundwater to form an aqueous solution. Depending upon the dissolved materials, the chemistry of this solution can vary. Where decaying vegetation makes a significant contribution to this solution, as in all temperate regions, it can become acidic. The reason for the acidity is that decaying vegetation produces carbonic acid, which can then drive dissolution of rock and soil surfaces on a large scale.

These and other chemical reactions weather the rock surfaces. This chemical weathering removes the less stable minerals and soils, leaving the more stable minerals behind. For the most part, the more stable minerals, such as quartz, feldspar, and clays are less damaging to the environment and human health. This is because they are less soluble but also because they are so common that life adapted to their presence. Through many millennia of weather-

Slag heap adjacent to a copper smelter in Greenwood, British Columbia, Canada (David Nunuk/Photo Researchers, Inc.)

ing, dangerous chemicals have been progressively removed from the surfaces of the rock exposures and all covering soils.

Mining removes material from underground, where it has not undergone this chemical refining, and places it on the surface, where it is bioavailable. There the abundant highly reactive minerals weather all at once. The dissolution reactions that take place on the fresh surfaces can release hazardous elements into the natural environment at rates that are orders of magnitude greater than those present in nature. This dissolution rate is further enhanced after the rocks have been broken and crushed during mining and processing of the ore. Natural rock surfaces tend to be large and smooth through the years of weathering. The smaller the size of the rock fragments and the more angular their surfaces, the greater the surface area that will be available for chemical reactions. By this process, the crushing of rock can also increase the weathering rate by further orders of magnitude.

Contributing to the pollution from mines more are the toxicity and abundance of the ore mineral itself. The only reason that a mine exists is to remove an economic concentration of a desired mineral. The mineral must be in much higher abundance than is normally present. Although some mined minerals are relatively safe in the environment, most are relatively dangerous. Ore prospects are commonly for their abundance of heavy metals, radioactive elements, asbestos, and sulfur, among other very toxic substances. Even relatively innocuous substances such as salt, lime, and alkalis can be damaging to the environment in high concentrations, especially when ground into a dust.

Water infiltrating mine tailings can produce acid drainage or runoff. Note the bluish color of the copper minerals in the rocks at the foreground. (Will and Deni McIntyre/Photo Researchers, Inc.)

One of the most environmentally damaging products of mining is acid mine drainage (AMD). The waters draining from the mine or percolating through the highly reactive tailings or waste piles can dissolve sulfur and produce sulfuric acid in the soil, surface water, and groundwater. This process is especially prominent in coalfields and sulfide deposits. Plants and animals cannot survive in such acidic conditions, and the area around such mines becomes ecologically damaged or dead. The acidity can further dissolve and strip heavy metals such as lead, copper, and zinc from the mine tailings and surrounding rocks, creating a toxic metal threat as well.

### BASIC TERMINOLOGY

Mineral deposits are those where the target mineral is in high enough concentration within a matrix of other minerals to be mined economically. The target mineral is the *ore*, and it can be metallic, nonmetallic, precious, strategic, or industrial. The minerals that accompany the ore but are not economic are called the gangue, and they must be separated from the ore during processing. To determine whether the concentration of the ore within the mined rock is economic,

it must be *assayed*. This is a chemical analysis to determine the percentage of ore in the rock, which determines its *grade*, a reflection of its *enrichment factor* relative to the average crustal composition. In a mineral deposit, not all of the rocks that are removed are of high enough grade to process. There may be no ore or not enough ore relative to the gangue. These waste rocks are dumped around the mines or where there is space as mine spoils, or *tailings*. In many cases, tailings are carted away and used in construction projects; depending upon the deposit, use of the tailings could be hazardous.

### TYPES OF ECONOMIC DEPOSITS

There are numerous types of economic deposits of minerals. The deposit depends upon the target mineral or material, as do the processes that formed it. Over the years, as the mining and extraction technology advanced, the types of deposits that can be mined economically have expanded significantly. Many current profitable mining operations would never have been considered in the past. Nonetheless, there are several categories of economic deposits that still apply today.

The first classification is based on the type of mineral to be mined. They are either metals or nonmetals. Metals can be abundant, such as iron, aluminum, and magnesium; scarce, such as zinc, chromium, and tin; or strategic, such as platinum, palladium, and rhodium, among others. Individual metals may switch categories with time depending on need. Nonmetal mineral ores may be used for chemical production such as salt (halite), sulfur, and borax; for fertilizers such as calcite (lime), apatite (phosphate), and sylvite; for building materials such as gypsum (plaster), clay, sand and gravel, and crushed rock; for jewelry such as diamonds, corundum (ruby and sapphire), and beryl (emeralds); and for ceramics and abrasives, among others.

The geologic classification of ore deposits is based on the processes that formed them and include igneous, sedimentary, weathering, and metamorphic.

### Igneous Processes

Igneous and sedimentary processes are the most common types. Igneous processes form most metallic and precious mineral deposits but may also form nonmetallic and industrial mineral deposits as well. The deposits from igneous processes include pegmatites, crystal settling, disseminated, hydrothermal, and volcanogenic.

#### Pegmatites

Pegmatites are very coarse-grained igneous rocks that cool underground directly from magma. They are mainly light-colored rocks that form by filling planar cracks and as such are typically tabular in shape. Pegmatites are the last bodies to form in igneous processes and, as a result, contain high amounts of water and other incompatible elements that are not common to igneous rocks. The water subdues nucleation of crystals, allowing the few that form to grow very large. One pegmatite from the midwestern United States had crystals up to 40 feet (12 m) long. The abundance of incompatible elements encourages the production of uncommon minerals, such as spodumene, a lithium-rich mineral, and tourmaline, a boron-rich mineral, among others. Pegmatites may also be mined for beryl (including emeralds), uranium minerals, garnet, mica, and feldspar, among others. Large mined pegmatite deposits occur in California, Maine, and Brazil.

#### Crystal Settling

The intrusion of mantle-derived mafic magma into the crust may produce a plutonic igneous body called a layered mafic intrusion. These bodies appear to intrude and cool slowly under quiet conditions of little additional magma or deformation. The crystalliz-

ing minerals can settle unimpeded through the liquid magma to the bottom of the magma chamber, where they can accumulate into an economic deposit. The most common ores to form by this process are platinum, chromite, nickel, and magnetite (iron). Large mined examples occur in Pennsylvania, Maryland, California, Montana, and South Africa.

#### Disseminated

Disseminated ores occur scattered in very small cracks and in spaces between mineral grains at the top of large igneous intrusions. These ores occur in low concentrations but over large volumes of rock. Sometimes referred to as porphyry deposits, disseminated ores can produce some of the largest accumulations in the world but spread out over so much gangue material that the cost of extraction may be excessive. Nonetheless, the Bigham Mine in Utah is a porphyry copper deposit that is the largest source of copper in the world. Its estimated value is \$6 billion.

Diamonds also occur as a disseminated ore, but their mode of formation is much different. They are formed deep in the Earth in the mantle (90–120 miles [150–200 km] deep), where pressures are extreme. They form in a gas-charged fluid-liquid-rock mixture that is gravitationally unstable. If fractures open above this mixture, they shoot explosively through the crust at speeds up to mach 2 and emplace in funnel-shaped pipes at or near the surface surrounded by crushed rock. The deposit is called a kimberlite, named after the classic example in Kimberly, South Africa, and it is the only source of diamonds. A kimberlite is the only way diamonds could make it to the surface because if they were raised up more slowly, they would convert back to graphite.

#### Hydrothermal

As the name implies, hydrothermal deposits are produced by hot aqueous fluids that transport the ore into a chemically favorable area. As a magma body cools and crystallizes, it releases massive amounts of very hot water. This water can dissolve and carry large amounts of metals and other ions but only as long as they are hot, under pressure, and in a certain pH range. As soon as they encounter other conditions, they precipitate the dissolved chemicals, primarily into cracks, faults, and pores, or they may even replace certain rocks by simultaneously dissolving them and precipitating the chemicals in their place. The replacement of layers of rock or sediment by hydrothermal fluids produces *stratabound* deposits that look like layering. The ore deposited in wide cracks forms tabular shaped *veins* that miners refer

**Diagram showing the enormous increase in total surface area of an object by breaking it into smaller pieces. Chemical reactions that release pollutants to the environment occur on the surface of mined rock.**

to as lodes. The most famous hydrothermal deposits form the Mother Lode gold-quartz ore in California, but many rich deposits of lead, zinc, and magnetite (iron) in many areas form this way.

### Volcanogenic

When volcanic activity occurs under the sea, chimneys, called black smokers, that constantly spew gas, fluid, and particles, are a common occurrence. Either these volcanic emissions deposit economic minerals directly on the seafloor, or the ocean water becomes saturated with metals and other ions, and they precipitate them onto the seafloor. The result is an interlayered sequence of volcanic rocks, deep sea sediments, and massive sulfides and base metals. The most common metal is copper, but zinc, iron, nickel, and magnesium are also possible. The best examples of volcanogenic deposits are the massive copper deposits in the island of Cyprus (whose name means “copper”).

### Sedimentary Processes

Sedimentary deposits are probably the most important of the mined economic materials. It used to be that all metals were from igneous deposits, but they are increasingly from sedimentary deposits as technology has progressed. There are also many minable deposits that are only from sedimentary rocks. There are two processes by which sediments are formed: They are transported and deposited either as particles or as dissolved elements and compounds.

### Precipitants

Dissolved compounds can be precipitated in shallow marine conditions and deep marine conditions. The processes for precipitation are supersaturation of water by dissolution of rocks and minerals enhanced by evaporation of the water from the solution and biologically enhanced precipitation. Some precipitation occurs in the open ocean, but, by far, most occurs in restricted basins with limited circulation. Even in open oceans, precipitation generally occurs in the deep oceans at the seafloor, where circulation is limited. The most common deposits are of rock salt, carbonates, and agates, mostly in warm areas such as the Gulf of Mexico. Manganese nodules are also deposited on the deep ocean floor. Shallow marine deposits include phosphates that are biologically enhanced and, in the distant past, banded iron formations (BIFs). These massive deposits occur in the upper Midwest and Canada and have provided most of the iron used in the United States.

### Evaporites

Even though evaporites form in a similar manner to precipitants by supersaturation of the water, in these deposits, evaporation from the Sun is the overwhelming process. Evaporites can form under terrestrial or restricted shallow marine conditions. In terrestrial conditions, evaporites can form in seasonal lakes and ponds or shallow seas that are cut off from the open ocean. Through evaporation, the waters supersaturate with ions and precipitate the

minerals, and some may be formed by chemical reactions after precipitation. Deposits may include gypsum (plaster), carbonates (lime), borax, and various alkali salts (including halite). There are large evaporate deposits in the Michigan basin and in the Basin and Range Province of the United States. The same minerals are found in shallow marine deposits, but they are typically in greater volume.

### Coal

Although coal would be better included in a discussion on energy, it is included here because it is mined. Today, there is more mining of coal in the world than all of the other types combined. Coal was mainly formed during the Carboniferous period of Earth history about 300–250 million years ago but also later in several areas. Coal forms when excess dead vegetation deposits in shallow water such as in swamps and other wetlands. With time, it is buried under sediments and compressed and heated. It first turns into peat and then into coal. Coal advances

through ranks from lignite to bituminous coal to anthracite with age and burial. The Appalachian Mountains and plateau (Allegheny) to the west produce anthracite, and the Rocky Mountains produce bituminous coal.

### Placer Deposits

Ores can be eroded from surface exposures of rock and carried as particles in surface water. Particles of many metallic ores are denser than the rest of the sediments carried by streams. Any section where stream flow slows, sediment particles are deposited in sand and gravel bars. The ore settles first by virtue of the density, and a higher percentage settles out than the other particle types. This process concentrates the ore particles into a small area called a placer deposit. The most commonly mined placer deposits are gold, platinum, and silver because they are dense. Diamonds may also form placer deposits, but they do not concentrate as the metallic ores do because diamonds are not so dense.

## OCCURRENCE OF METALLIC MINERALS

Metal	Principal Ores	Geological Occurrences
Aluminum	Bauxite	From residual weathering
Chromium	Chromite	Settling in magma; differentiation during cooling
Copper	Chalcopyrite, bornite, chalcocite	Hydrothermal deposits; contact metamorphism
Gold	Native gold	Hydrothermal deposits; placers
Iron	Hematite, magnetite, limonite	Banded formations; magmatic segregation; hydrothermal
Lead	Galena	Hydrothermal deposits
Magnesium	Magnesite, dolomite	Hydrothermal deposits
Manganese	Pyrolusite	From residual weathering
Mercury	Cinnabar	Hydrothermal deposits
Molybdenum	Molybdenite	Hydrothermal deposits
Nickel	Pentlandite	Settling in magma
Platinum	Native platinum	Settling in magma; placers
Silver	Native silver, argentite	Hydrothermal deposits; enrichment by weathering
Tin	Cassiterite	Hydrothermal deposits; placers
Titanium	Ilmenite, rutile	Settling in magma; placers
Tungsten	Wolframite, scheelite	Pegmatites; contact metamorphism; placers
Uranium	Uraninite (pitchblende)	Pegmatites; sedimentary deposits
Zinc	Sphalerite	Hydrothermal deposits

### **Sand and Gravel**

Particles of sediment that are not economic in their own right can concentrate to form sand and gravel deposits, which are economic. Sand and gravel are concentrated in several sedimentary processes, most notably in streams and in glacial outwash deposits. As such, they are more common in the northern United States than in the South. Sand and gravel are not particularly rare, but they are used in massive amounts in construction projects involving poured concrete and asphalt including those in all cities. The problem is that transporting all of the necessary sand and gravel great distances from the source to the cities is very expensive. Deposits closer to cities are worth a lot of money.

### **Clay**

Although not readily apparent, clay is a high-volume industrial mineral. It is used in cat litter, for the slick coating on paper, in china and other ceramics, and in bricks. Clay is deposited in great volumes on the ocean floor, but it is not available for mining. Shallow water deposits are less common because they require areas with very low energy conditions with no input of sand or gravel. Clays are mostly taken from lagoons and bays in marine settings, lake deposits and especially glacial lakes, and some floodplain deposits around rivers. Clay deposits in Georgia are called “white gold” because they are worth so much money, but clay deposits are not uncommon.

### **Weathering Processes**

There are certain weathering processes that remove minerals by chemically dissolving them and transporting them away. This redistribution of elements and compounds forms the basis for the formation of economic deposits through weathering. Though not nearly as important as igneous and sedimentary processes, weathering processes, nonetheless, form some economically important deposits.

### **Laterites**

The deep weathering of soils in tropical climates with high precipitation strips away many of the unstable and even relatively stable minerals. The warm temperatures and abundant acidic waters enhance chemical alteration and dissolution. The speed at which removal takes place is a measure of chemical mobility. Immobile elements and compounds are those that are left behind. Under these conditions, none is more immobile than aluminum, which accumulates in lateritic soils, forming bauxite. Bauxite is aluminum ore that is mined in the Tropics.

### **Secondary Enrichment**

The fluids that dissolve compounds during weathering can redeposit it if conditions are favorable. In many cases, oxidized elements are mobile, and reduced elements are immobile. Fluids carrying dissolved ions can percolate through sediments and soils with minimal exchange of ions until they encounter a reducing environment. Such environments might be limestone- or organic-rich deposits such as shale, coal, or biomass. The chemical reactions, in this case, can precipitate the dissolved ions upon contact. Certain bacteria can enhance this process, as well. There are many examples of such interactions such as the petrified forest of Arizona and sulfide deposits in many swamps. The most economic example is that of uranium, which has been found to deposit on buried logs and other vegetation and in clays, among others.

### **Metamorphic Processes**

Metamorphic processes are the least important for the generation of ore. There are many economic deposits in metamorphic rocks, but the majority of them were emplaced while the rocks were igneous or sedimentary. Hydrothermal activity can occur in metamorphism, as well as in igneous processes, and produce similar deposits. There are a few processes that are unique to metamorphism that tend to produce useful minerals and possibly even some metal deposits.

### **Contact Metamorphism**

If a magma body intrudes crustal rocks, it metamorphoses the rocks around it. This metamorphism imposes no change in pressure but radically changes the temperature and the fluids. The volume of rock affected by the body is called the aureole and undergoes contact metamorphism. Economic deposits of minerals can be produced in the aureole depending upon the composition of the rock that was intruded. The best rock to intrude for deposits is limestone. Not only can minerals with useful elements such as tungsten and molybdenum form, but minerals with useful properties may also form. For example, wolastonite is a bladed mineral that is used as filler in car body panels. Shales may also form useful minerals through contact metamorphism such as emery deposits (corundum), which are used as excellent abrasives.

## **TYPES OF MINING OPERATIONS**

There are basically two types of mining operations, surface and underground. There are several types of each of these depending upon the type of matrix around the ore. The choice of the type of mining employed depends upon numerous other factors

### OCCURRENCES AND USES OF NONMETALLIC MINERALS

Mineral	Uses	Geological Occurrences
Apatite	Phosphorus fertilizers	Sedimentary deposits
Asbestos (chrysotile)	Incombustible fibers	Metamorphic alteration
Calcite	Aggregate; steelmaking; soil conditioning; chemicals; cement; building stone	Sedimentary deposits
Clay minerals (kaolinite)	Ceramics; china	Residual weathering
Corundum	Gemstones; abrasives	Metamorphic deposits
Diamond	Gemstones; abrasives	Kimberlites; placers
Fluorite	Steelmaking; aluminum refining; glass; chemicals	Hydrothermal deposits
Garnet	Abrasives; gemstones	Metamorphic deposits
Graphite	Pencil lead; lubricant; refractories	Metamorphic deposits
Gypsum	Plaster	Evaporite deposits;
Halite	Table salt; chemicals; ice control	Evaporite deposits; salt domes
Muscovite	Insulator in electrical devices	Pegmatites
Quartz	Glass	Hydrothermal; sedimentary deposits
Sulfur	Chemicals; fertilizer manufacture	Sedimentary deposits; hydrothermal deposits
Sylvite	Fertilizers	Evaporite deposits
Talc	Paints; cosmetics	Metamorphic deposits

besides the type of ore and gangue. Factors include shape and depth of the ore body, population density around the mined area, grade of the ore, regulations on mining in the area, available technology, and the amount and depth of surface water and groundwater in the area. Most mining is underground unless the ore body is shallow, economic, and extensive and all of the other listed limiting factors are minimized.

#### Underground Mines

Underground mining techniques must be employed if the ore body extends to a significant depth. Vertical and subvertical ore bodies must also be accessed by an underground mine, though the top of the body may be surfaced mined as well. In most cases, however, a tunnel must be cut to the ore body before large-scale mining can begin.

The tunnels to access the ore body are most commonly declines, shafts, or adits. Declines are usually inclined spiral tunnels that circle either the flank of the deposit or the deposit itself. They begin at the surface or in a surface mine with a box-cut portal

to the surface and may be lined with a galvanized steel culvert for safety purposes. Shafts are vertical tunnels adjacent to the ore body that are serviced by using elevators. Shafts are preferred for ore bodies where haulage to the surface using trucks is not economical. Adits are horizontal tunnels into the side of a hill or mountain that are used for horizontal or near-horizontal ore bodies.

Once the access tunnels reach the ore body, there are several methods of mining it. Room and pillar mining consists of intersecting cavities, or rooms, with pillars of rock that hold up the roof. The pillars are later mined when that part of the mine is closing. Longwall mining is accomplished using a machine called a continuous miner that cuts layers of coal or minerals from the walls. There are several tactics in moving through the ore body with regard to the waste rock generated. In stope and retreat mining, rocks are extracted from the stopes (rooms) without filling the open voids. This method allows the wall rocks to cave in to the void after the ore has been removed. The stope is then sealed. In contrast, in stope and fill, after

the ore is removed, the open stope is backfilled with a cement and rock mixture, a cement and sand mixture, or a cement and tailings mixture. Cut and fill mining is similar to stope and fill but with a short hole in narrow ore zones. An access ramp is cut into the bottom of the ore zone, and a drift is driven through the ore. The drift is then backfilled to the access ramp. Drift and fill is similar to cut and fill, but it is used in ore bodies that are wider than the drifting method allows. Block caving is used with large ore bodies of low-grade, friable ore. Blasted ore is removed underneath the friable ore until an area of unsupported ore begins to fracture and cave in on its own.

### Hard-Rock Mining

Hard-rock mining is underground mining into solid or crystalline bedrock. An opening called an adit is excavated at the surface. Tunnels extending from the adit and into the rock are drilled out and blasted with dynamite. The tunnels, called shafts, are cut vertically downward into the rock until they encounter the ore body. Numerous shafts are cut for miners to use to go into and out of the mine, for mine machinery, and for ventilation. The tunnels in hard-rock mines generally use room-and-pillar techniques. Ores in hard-rock mining contain metals such as gold, copper, zinc, nickel, and lead or gems such as diamonds, emeralds, and rubies.

There are several ways to access and mine the ore in underground mining. The opening in a *shaft mine* is made by opening a vertical tunnel downward to the elevation of the coal seam. Short tunnels to the ore are dug from the main shaft. Mining is conducted by using typically either longwall mining or room-and-pillar mining with continuous mining equipment. The ore is dynamited, broken into chunks, and taken to the top to be loaded onto trucks. With *slope mining*, the ore layer is located very deep and is horizontal or subhorizontal. It is called a slope mine because the access shafts are slanted and sloping. This kind of mining is preferred if there are difficulties drilling shafts straight down. Slope mines are usually relatively shallow in the earth.

Drift mines are a form of underground mining that is done when the ore is on the side of a hill or mountain and accessible by using horizontal tunnels. The tunnels that are horizontal are called drifts. If possible, the drift is dug a little lower than the ore body. This makes it easier to take the materials out because gravity helps move them downhill.

### Borehole Mining

With borehole mining, a shaft or tunnel is drilled deep enough into the ground to reach the ore body. A long tubelike tool is lowered into the hole. The tube has places for water to be forced out of holes or ports and other places where the water can be pushed back up the tube. The water is forced down this tube, and the stream breaks up the dirt and rock. The water combines with the dirt, rock, and minerals to make a combination called a slurry. The slurry is pumped back up to the surface, where it is put into a storage tank. The water is drained and the ore is taken out of it.

### Surface Mines

Surface mining techniques must be used in some cases and can be used in others. The most common surface mines are strip mines. In this case, all of the rock above the ore (overburden) is removed by using heavy machinery and dumped.

### Strip Mining

In strip mining, a very shallow ore seam is first exposed by removing all of the overlying soil and rock, otherwise known as the overburden. The ore is then excavated and removed from the surface. Strip mining is most commonly used to mine coal or tar sand. Strip mining is only practical when the ore body is near the surface. This type of mining uses some of the largest machines on Earth, including bucket-wheel excavators that can move as much as 412,000 cubic feet (12,000 m<sup>3</sup>) of earth per hour.

There are two types of strip mining, area stripping and contour stripping. The more common method is *area stripping*, which is used in relatively flat areas, to extract ores that cover a large area. As each strip is excavated and removed, the overburden is backfilled into the excavation from the previous strip. *Contour stripping* involves removing the overburden above the ore body near its outcrop in a hilly or mountainous terrain, if the outcrop of the ore follows the contour of the land. Contour stripping commonly leaves behind terraces in mountainsides and hillsides.

### Open-pit mining

Also known as opencast, open-cut, and strip mining, open-pit mining is a method of extracting ore by removal from an open pit or borrow. Open-cut mines are excavated on benches equivalent to vertical levels of the hole.

(*opposite page*) Block diagrams showing the two major types of mining: underground (subsurface) and strip mining. Underground mining is for deep-seated ore and leaves a maze of tunnels underground and piles of waste rock on the surface. Strip mining is for shallow ore and removes the entire surface.

**Mountaintop removal (MTR) mining**

A relatively new form of mining for coal, in which there is massive restructuring of the surface in order to reach the coal seam, which may be as deep as

1,000 feet (308 m), is mountaintop removal mining. It is used where the outcrop of the coal seam completely encircles a mountain. All of the rock and soil above the coal seam are removed and dumped

**A Underground (subsurface) mining****B Strip mining**

into adjacent hollows and ravines and any other low spots. Mountaintop removal replaces mountains with relatively level surfaces.

### Highwall Mining

Another form of surface coal mining, highwall mining is a variant of surface auger mining. In highwall mining, the coal seam is continuously excavated by using a piece of hydraulic equipment called a push-beam transfer mechanism (PTM) that cuts into and strips out the ore.

### Dredging

Dredging is a method that is commonly used to excavate underwater mineral and ore deposits, and especially placer deposits. Dredging is usually used to clear or enlarge channels for boats in major waterways, but it can also be used to recover underwater ores in a relatively cheap and efficient manner. Depending upon the deposit, dredging can be done by using large channel dredging equipment or a small floating vacuum.

### Gold Mining

Gold mining is considered as a special case because there is a chemical method that was used in many areas. In placer deposits, much of the gold is not in pure form but instead occurs in particles with gangue minerals. In order to remove the gold from the waste rock, mercury can be mixed with the particles; the mixture then strips out the gold to form an *amalgam* that can be easily separated. A chemical process to remove the mercury is applied later. This method was heavily used in the second half of the 19th century in California, where 0.75 pound (0.34 kg) of mercury was introduced to the environment for every 1,000 pounds (455 kg) of ore processed. In all, about 12 million pounds (5.5 million kg) of mercury was released into the surface waters surrounding the famous Comstock Lode of Nevada during gold mining operations. This caused heavy mercury pollution (on average, 10–100 times background levels) that is still causing problems today. Replacing the mercury amalgam method was cyanide leaching, which began around 1900. This method can be used at the mine or later in processing.

After mercury processing was abandoned in the United States, in order to remove the gold from the gangue minerals and metals, a process called cyanide leaching was discovered in 1887. The ore was soaked in cyanide, which dissolved the gold into solution. Zinc shavings were then added to the solution. The zinc shavings bonded with the gold, and the cyanide solution could be drained away. The shavings were then heated and the zinc vaporized, leaving the gold

as a residue. The method is basically the same today, but miners now use a process called heap leaching, in which the cyanide solution is drained through a pile, or heap, of ore and collected below. The problem, of course, is that cyanide is a poison deadly to both humans and wildlife. Any release has dire consequences.

## EXAMPLES OF POLLUTION FROM MINES

The Panguna Mine in Bougainville, Papua New Guinea, was one of the most polluted mining areas in the world until it closed in 1989. The aggressive mining operation extracted copper sulfide ore for processing and dumped an average of 600 tons (545 metric tons) of tailings into the Kewerong River per year. The waste rock covered seven square miles (1,800 ha) of the river system, including the 2.7-square-mile (700-ha) delta. Infiltration and dissolution of the sulfur-rich tailings by precipitation and surface water resulted in acidic surface water and groundwater. The low pH killed all of the aquatic life in the surface waters and infuriated the local residents. An article in the commercial mining trade press (*Trading Markets*) clearly characterized this flagrant environmental destruction as one of the major causes of an ensuing civil war: “The mine closed in 1989 as the Papua New Guinea island descended into secessionist conflict spurred by land-owner issues and the environmental damage the mine was causing.”

The island of Nauru in the South Pacific had a large phosphate prospect that was first mined in 1906 by Germans. Through most of its history, it was part of Australia, which destroyed the land in an attempt to remove all of the phosphate. The residents of Nauru won a major legal battle against Australia over the environmental damage. Most of the large-scale mining ended in 2008, but more than 80 percent of the eight square-mile (2,100-ha) island has been damaged or destroyed by the mining.

The Summitville Mine complex in the San Juan Mountains of Colorado has a twofold environmental problem. It is a gold mining complex, and there are other heavy metals associated with the ore. Gold was first discovered at Summitville, in 1870, and there was significant gold production from underground workings prior to 1900. In 1903, the Reynolds adit was built to drain the mine and serve as an ore haulage tunnel to renew production, which occurred sporadically through the 1950s. Production basically ended afterward, but as a result of new advances in separation techniques using cyanide heaps, in 1984, open-pit mining of gold ore from waste rocks surrounding the old underground work-

ings was renewed. The new techniques and rising price of gold made it economic to process ores where gold concentrations had been previously too low. The environmental problems of the mine surfaced in 1992 and 1993, when the cyanide solutions began leaking into the surface water and groundwater systems of the area. A full investigation of the area released in 1995 found that the cyanide was a minor problem compared with the acid-generated heavy metal contamination, which poisoned 17 miles (27 km) of the Alamosa River. The U.S. Environmental Protection Agency placed the site on the National Priorities List in 1994, even before the report was released. Cleanup of the site is costing about \$120 million.

Environmental problems with mines are not restricted to exotic or isolated areas. The U.S. Environmental Protection Agency recently concluded that “over 95% [of the Mid-Atlantic states acid mine drainage problem] is located in western Pennsylvania, . . . West Virginia . . . southeastern Virginia . . . and far western Maryland.” There is even a case of acid mine drainage in Garrison, New York, about 35 miles (56 km) north of New York City. The deposit was first mined for copper, but the main ore quickly became the massive sulfide deposit. It was mined during the late 19th century, and the ore was loaded onto barges in the Hudson River 0.5 mile (0.8 km) downhill and taken to Staten Island for processing into sulfuric acid. The mine was abandoned by 1900, but the exposed sulfide-rich tailings have been weathering since. Surface water and groundwater that infiltrate the tailings piles and dissolve the sulfides, producing acid mine drainage with pH as low as 1.78. There is no vegetation growing on the tailings and mine soils. The acid strips out heavy metals from the tailings and contaminates the groundwater and surface water in the area.

### TRANSPORTATION OF ORE

Once removed from the mine, crushed, and separated, most metallic ore must be transported to a furnace or foundry for processing. The most common method of long-distance transportation for bulk ore is by rail or by barge if the mine is on a navigable river. Local transportation is done by truck, depending upon the product.

The main issue with pollution from transportation of ore results from accidents and incidental loss from material blown off the transportation system. Railroad lines that are used to transport coal are invariably covered in a fine coating of black coal soot. The extent of the loss depends upon the speed of the train, condition of the rails and train, and strength of prevailing winds. The pollution from this

source is not a major concern in almost all cases. Transportation loss and windblown loss of phosphate, however, can produce problems. Rail lines from phosphate pits in Florida cross Georgia and Alabama. Significant amounts of phosphate have blown off the open cars for more than 50 years. Vegetation around the lines is lush from the fertilizer effect of the phosphate, which also enhances eutrophication in nearby rivers and ponds. Phosphate minerals are also enriched in uranium and radium. The soils around the current and closed rail lines contain high levels of radon, which can affect the indoor air quality in nearby homes. Windblown asbestos and lead, among others, from train cars and trucks can also lead to public health concerns.

### BASICS OF SMELTING AND REFINING

Some ore is used as is or with minor processing such as separation and crushing. Most evaporites and minerals used for their physical properties such as asbestos, garnet, and other abrasives and wollastonite are in this category. Other ores must be chemically altered before they can be used. Most metals are contained in compounds and must be chemically separated from other elements before they can be used. Only metals in their native form such as gold, silver, and some copper and iron do not require appreciable processing. There are several basic steps in the smelting and refining process.

The first chemical processing of ore is smelting in a furnace. Three ingredients are needed for this: ore, fuel, and flux. The location of furnaces is usually convenient to the source of fuel, which has been coal for at least a century. Before that, charcoal was also commonly used. The fuel is burned in a furnace with air pumped in to increase the temperature. The ore is then dumped in with a flux to drive a chemical reaction to remove the unwanted elements and compounds from the ore in this molten state.

To make iron, the ore is either magnetite or hematite, both of which are iron oxides with varying valence states. To make pure iron, the oxygen must be removed and the ore reduced. The flux for this reaction has been limestone since ancient times. The limestone is first crushed and baked (calcined) before being added to the furnace. Once it is in the furnace, a reaction takes place:

The volatile compounds  $\text{CO}_2$ ,  $\text{O}_2$ ,  $\text{H}_2\text{O}$  boil off to the atmosphere, the molten iron goes to the bottom of the furnace, and the slag, which is a compound of leftover elements, rises to the top, where it is

skimmed off and disposed of. In historical times, the liquid iron would have been decanted off to a casting room with a sand floor. It flowed along a main channel and off into ingot-shaped hollows, where it cooled and hardened. The shape looked like piglets (ingots) suckling on a sow (main channel), and, as a result, it was called pig iron. This iron has a lot of impurities and must be refined before it can be used for anything useful. In ancient times, it was beaten into an object, but later it went to a steel mill. Iron production, although principally the same, is far more sophisticated, producing high-quality steel in a single process.

Although the mining and infrastructure can be damaging, the by-products of iron production are relatively benign to the environment and public health. The production of other metals, however, can be quite damaging. One of the most damaging ores is sulfide. Much of the lead, copper, and zinc ore occurs in the form of sulfides. The sulfur must be removed from the metal in smelters to produce economic metals. For most of history, the sulfur compounds were released to the atmosphere from smokestacks and settled to the ground around the smelter or contributed to acid precipitation somewhere else. In some historical smelters, the sulfur was recovered and sold, and, today, filters are required by law to prevent the release of sulfur. In the vast majority of the smelters, the sulfurous fallout made the soil and surface water so acidic that it killed all life in a significant area around the plant.

### EXAMPLES OF POLLUTION FROM SMELTING AND REFINING

There are numerous cases of profound pollution from smelter operations. Perhaps the most impressive of these is in Sudbury, Ontario, Canada, where nickel and copper sulfides have been smelted adjacent to the mine complex. As the result of sulfuric acid fallout, a vegetation dead zone developed around the smelter complex and reached 40 square miles (10,400 ha) in size. Fish and other animal populations were completely eliminated within a 40-mile (65-km) radius of the smelter. The government undertook an aggressive  $\text{SO}_2$  reduction program including the building of the world's tallest smokestack, and the area has recovered over the past three to four decades.

Another example of profound pollution caused by smelting and refining operations is Norilsk Mining and Smelter in Norilsk, Siberia, Russia. The mines yield nickel, copper, and other metallic elements to form concentrated deposits of sulfides. Estimated reserves for the deposit are almost 2 billion tons (1.8 billion metric tons), which are removed from

underground mines that extend more than 3,900 feet (1,200 m) belowground. These ore deposits were known for many years, but mining operations did not begin until around 1935 and continue today. The environmental effects of smelting the ore in the facilities adjacent to the mining operation are severe. An area with a roughly 25-mile (40-km) radius around Norilsk is ecologically dead, all of the trees and other vegetation killed by acid rain. The landscape is scarred with open pits and piles of waste rock and debris. In some places, the upper few feet of soil is so heavily contaminated by fallout of nickel and copper that it is economic to mine. Almost 15 percent of all the industrial pollution in Russia is produced by the Norilsk plant, as its main Nadezhda Metallurgical facility has emitted more than 2 million tons (1.8 million metric tons) of sulfur dioxide into the atmosphere every year since 1950. Wastewater used in ore processing is discharged without treatment into surface water bodies and has contaminated more than 60 miles (100 km) of streams and rivers. It is estimated that annual discharge of unprocessed industrial sewage from Norilsk smelters and mines into the sensitive Siberian ecology is more than 500 million gallons (1,893 million L).

There are also profoundly contaminated sites in the United States. The Bunker Hill Mine Superfund Site of Shoshone County, Idaho, is a prime example. The first mines that extracted lead and silver ores opened in Shoshone County in 1889. At peak production, the mine area covered 6,200 acres (2,509 ha), was more than one mile (1.6 km) deep, and had nearly 125 miles (201.2 km) of underground roads, adits, and shafts. Much of the smelting and refining was done on the premises. During the 1970s, the Bunker Hill smelter was the second largest in the United States, producing more than 20 percent of the country's lead and zinc and nearly one-fifth of the processed lead in the world. Between 1965 and 1981, the smelter released more than 6 million pounds (2.7 million kg) of lead into the atmosphere. During processing of the ore, large amounts of lead dust were emitted but quickly settled around the mill, where they contaminated the soil, washed into surface water, and leached into underlying groundwater. The lead in this airborne dust represented a serious threat to the health of workers and local residents. The Bunker Hill Complex was declared a Superfund site in 1983 and has been undergoing extensive remediation ever since.

There are many other examples around the United States of problems produced by the smelting of sulfides. Two of the most infamous are in Ducktown, Tennessee, and Palmerton, Pennsylvania. Both destroyed the ecology of the area around the smelters by producing severe acid and metal fallout and

**Diagram showing the steps in refining from mining the ore to the pure metal for manufacturing. Each step produces its own emissions of pollutants, most of which create the worst types of pollution in the world.**

acid precipitation similar to those in Sudbury and Norilsk. Ducktown was a copper-lead prospect, and Palmerton was built to process the zinc ores from Franklin, New Jersey. Both are long since closed; the areas were remediated and have recovered on their own to some extent, but pollution issues remain after all of this time.

**mold** Lately, mold has become a newsworthy pollutant because many public buildings are being closed to treat mold. Schools have been especially vulnerable to it, and numerous academic programs have been disrupted to allow workers to remediate the problem. For this reason, mold has become one of the most addressed indoor pollutants of the 21st century. Perhaps this interest is long overdue, as mold and mildew are becoming increasingly prevalent in homes, as well, to the point where the number of people sensitive to them is increasing dramatically. Mold and mildew may be partially responsible for the current increase in respiratory illnesses among children. They can infect an entire house and require many thousands of dollars for removal. There are several factors in the life cycle of mold and mildew that make them such a health threat, especially their method of reproduction and their preferred habitats.

### SOURCE AND DISTRIBUTION

Mold and mildew are members of the fungi kingdom, which also includes mushrooms and yeast. There are between 50,000 and 250,000 species of fungi, but fewer than 200 have the ability to cause infections in humans. There have been more than 1,000 species of mold found in homes within the United States, but only a few are associated with health problems. It is the reproduction process of mold that makes it a health concern. As with other fungi, mold reproduces by releasing spores. The spores are light enough to travel through air and resistant enough to survive many adverse conditions. They can, therefore, become a significant component of indoor air pollution, where the enclosed space with limited circulation prevents dilution with fresh air as in outdoor conditions.

Another reason that mold and mildew are so successful in homes and buildings is that they thrive in wet, moist, and humid conditions. They can grow on

dust particles, paints, wallpaper, insulation, ceiling tiles, wood, paper, cardboard, carpet, upholstery, fabric, and foods. They grow wherever there are significant moisture and sustenance, including in kitchens, bathrooms, humidifiers, and dehumidifiers; around pipes, leaky roofs, and vents; and in some heating and air-conditioning systems. They are also common on the exterior wall surfaces of corner rooms in climates where heating is required as a result of condensation, and they create particular problems after any type of flooding. The resulting indoor mold and mildew after a minor flood can cause almost as much damage as the water itself.

Mold and mildew enter a building through open doorways, windows, vents, and some heating and air-conditioning systems, or they can be carried in on clothing, shoes, pets, firewood, and other items that have been exposed to outdoor air. Once inside, new tightly sealed buildings that do not allow moisture to escape make perfect incubators for the growth of mold and mildew. That is one reason that the mold and mildew problem has increased over the past few decades. The other reason is that delayed or insufficient maintenance can encourage growth as well. Temporary structures such as trailers and portable classrooms are also particularly susceptible to problems; that is another reason that it is showing up in schools with such regularity.

### HEALTH EFFECTS FROM EXPOSURE

For the people who are sensitive to mold and mildew, in most cases, exposure results in nasal stuffiness, throat irritation, coughing or wheezing, eye irritation, or, in some cases, skin irritation. There are, however, several types of mold that may have different effects on different people, including severe effects. The term *toxic mold* used to describe severe effects is a misnomer. They can produce toxins and especially mycotoxins, but the mold itself is not toxic or poisonous. In fact, bread mold was the origin for penicillin, which began antibiotic medicines and the ability to fight infection. In that regard, mold has benefited far many times more people than it has damaged.

The most common types of molds are *Cladosporium*, *Penicillium*, *Aspergillus*, and *Alternaria*; *Stachybotrys chartarum* is less common. *Aspergillus fumigatus* or *A. flavus* can be dangerous to certain groups. In people who have immunosuppression disorders, complications induced by mold may include invasive pulmonary infection, usually with fever, cough, and chest pain; the infection may spread to other organs including the brain, skin, and bones. People who have chronic obstructive

pulmonary disease (COPD) or other lung diseases including asthma may contract localized pulmonary infections. People who have severe, prolonged granulocytopenia, such as hematologic malignancy; hematopoietic stem cell or solid organ transplant recipients; and patients on high-dosage corticosteroids are at high risk for mold-related complications. Persons who have human immunodeficiency virus (HIV) infections may also be at risk. If severe disseminated infections persist, the mortality rate can be very high for many patients and 100 percent for those who have cerebral abscesses.

A specific disease caused by repeated exposure to mold is called farmer's lung. It is a form of hypersensitivity pneumonitis that is caused by the species *Thermoactinomyces vulgaris*, which is a fungus found in moldy hay or straw or on grain dust. Farmer's lung occurs in 0.5–9.6 percent of farming populations and has been reported in the United States, Canada, France, Norway, Sweden, and parts of several other European countries.

The less common species *Stachybotrys chartarum*, also known as *Stachybotrys atra*, is a greenish black mold that was potentially linked to an outbreak of pulmonary hemorrhage or idiopathic pulmonary hemosiderosis in very young children in 1994. In addition to this condition of acute bleeding from the lungs, a connection between mold exposure and memory loss and lethargy has been proposed but not verified. There is also a strong indication that mold may produce some types of cancer. Aflatoxins and ochratoxin A are toxins produced by mold that have been classified by the National Institutes of Health, National Toxicology Program as human carcinogens. Cancer of both the liver and kidneys has been shown to be significantly increased by long-term repeated ingestion of these toxins. This is one of the few cases of health issues related to mold in which the exposure is not through inhalation.

### MOLD PREVENTION

There are no regulations regarding acceptable levels of mold in homes and buildings. There are mold spores in most homes. The goal is to prevent them from forming surface colonies. Humidity should be kept between 40 and 60 percent, and mold inhibitors should be added to paints in moist rooms. Otherwise, all wet areas should be dried as soon as possible and mold and mildew should be washed away. Ventilation systems should also be cleaned and treated regularly. These prevention steps are especially important in homes where people are at high risk for infection.

**Molina, Mario J. (1943– )** *Mexican Environmental Chemist* There are only a few cases when a scientific researcher finds the cause of a major global problem, and the whole world acts to address it. This, however, is exactly the case for Mario Molina. He began research on a relatively bland topic of chlorofluorocarbons (CFCs) and their interactions with atmospheric gases in 1973. It was a relatively open field because CFCs are relatively inert in the lower atmosphere and few researchers expected any interesting science from it. Even though he had no reason to believe that these inert chemicals were a problem, Molina showed that at high altitudes solar radiation could dissociate the CFCs, producing free chlorine radicals. It was these chlorine radicals that Molina and his associate F. Sherwood Rowland believed would catalytically destroy ozone. They published their results on June 28, 1974, in the prestigious journal *Nature* to moderate interest.

It was in 1984 that several scientists were shocked to discover a huge hole in the ozone layer over Antarctica. Although CFCs had already been implicated in ozone depletion both by Molina and by subsequent researchers, some people still did not believe that CFCs were the cause of the problem. Mario Molina went back to his lab and proved that CFCs were the cause and developed a full model to explain the process. As a direct result, CFCs were immediately banned from many applications such as aerosol propellants and phased out of others such as refrigerants on a nearly global basis. As a result of this scientific research, society was changed. For his efforts, Mario Molina received the 1995 Nobel Prize in chemistry, which was shared with F. Sherwood Rowland and Paul Crutzen, another researcher of ozone depletion.

In addition to his groundbreaking work on ozone, Mario Molina works on the chemistry of aerosols in the atmosphere and photochemical reactions in the atmosphere. He is also considered an expert on air pollution over megacities in the developing world. Considering that he grew up in Mexico City, one of the most notorious examples of a highly polluted megacity, his research interests are not surprising.

### BIOGRAPHICAL INFORMATION

Mario J. Molina was born on March 19, 1943, in Mexico City, Mexico. His father, Roberto Molina Pasquel, was a lawyer and university instructor, who later served as the Mexican ambassador to Ethiopia, Australia, and the Philippines. Mario Molina attended elementary school in Mexico City and lived quite comfortably. His aunt, Esther Molina, was a chemist, and he developed his love of chemistry through her. When Mario was 11, he was sent away to boarding school in Switzerland but was dismayed when his classmates there had no more interest in science than his friends in Mexico. In 1960, he completed high school and enrolled in the chemical engineering program at the Universidad Nacional Autonoma de Mexico, the same school where his father had taught. He would have preferred to study physical chemistry, but it was not offered. When he graduated in 1965, Mario decided to earn a Ph.D. in physical chemistry and enrolled in the University of Freiburg in Germany. After two years of study, he found that the direction he was following was not to his liking and withdrew from the program. He returned to the Universidad Nacional Autonoma de Mexico as an assistant professor in chemical engineering and even began a graduate program for the department but again decided to leave.

In 1968, Mario Molina decided to pursue his true interest in physical chemistry and entered the Ph.D. program at the University of California at Berkeley. He found the exact area that he wished to pursue under the mentorship of George Pimentel. He studied molecular dynamics using chemical lasers in a very active research group that included Luisa Tan, whom he would later marry. He completed his Ph.D. in 1972 and accepted a postdoctoral fellowship from his adviser for an additional year. In fall 1973, Mario obtained a second postdoctoral fellowship, at the University of California at Irvine under F. Sherwood Rowland. It was there that he began his groundbreaking work on CFCs. In 1975, he was appointed to the faculty at the University of California at Irvine as an assistant professor and later associate professor. With all of the teaching

and administration that accompany a faculty position, Mario missed experimental work, so, in 1982, he accepted a position in the molecular physics and chemistry section at the National Aeronautics and Space Administration's (NASA's) Jet Propulsion Laboratory at California Institute of Technology.

By 1989, Mario Molina found that he missed the academic life and joined the faculty at the Massachusetts Institute of Technology as a full professor. In 1997, he became the Lee and Geraldine Martin Professor of Environmental Sciences and remained until 2005. At that point, he was divorced from Luisa Molina and married Guadalupe Alvarez. He also accepted the position of professor at the University of California at San Diego, where he remains today. Another current project of his was the creation of a new center for strategic studies in energy and environment, which Dr. Molina is heading.

### AWARDS

Certainly, the most prestigious award that Mario Molina has received for his work was the 1995 Nobel Prize in chemistry. This is not the only honor he received. In 1994, Molina was named by President Bill Clinton to serve on the 18-member President's Committee of Advisers on Science and Technology. In 1998, he was named as one of the top 20 Hispanics in Technology. In 2003, he received the Ninth Annual Heinz Award for environmental protection and was named one of the outstanding "trailblazers" in science by *Science Spectrum* magazine in 2005. Molina is a member of the U.S. National Academy of Sciences, the National Institute of Medicine, and the Pontifical Academy of Sciences. He has served on the Secretary of Energy Advisory Board, the National Research Council Board on Environmental Studies and Toxicology, and the boards of the U.S.-Mexico Foundation of Science. He was the first person not living in Mexico ever to be inducted into the Mexican National Academy of Engineers.

**MTBE (methyl tert-butyl ether)** The history of MTBE is quite ironic. MTBE is primarily a fuel additive designed to reduce air pollution, and yet this remedy itself has become an environmental threat. MTBE was introduced in 1979 as an additive to gasoline as a replacement for lead to boost octane. The concentration was greatly increased in 1992 in certain areas to oxygenate the fuel. MTBE raises the oxygen content of the gasoline to help it burn more completely, thus reducing harmful emissions. In the beginning, it was only used in winter months. In 1995, however, to fulfill the requirements of the 1990 Clean Air Act Amendment, reformulated gasoline was required on a year-round basis in certain cities with the highest ground-level ozone concentrations. At that point, about 30 percent of the gasoline sold in the United States had to be reformulated, and of that, about 87 percent was treated with MTBE to resolve the problem. The second phase of the reformulated gasoline program, which expanded the use of MTBE further, began in January 2000. The U.S. Environmental Protection Agency (EPA) reported that as a result of this program, at least 105,000 tons (95,454 metric tons) of smog-forming pollutants and 24,000 tons (21,818 metric tons) of airborne toxins was being reduced annually in the United States, the equivalent of taking 16 million cars off the road. The requirements are that refineries must effect a reduction of volatile organic compounds (VOCs) by 27 percent, airborne toxins by 22 percent, and nitrogen oxides by 7 percent, compared with the gasoline they produced in 1990. MTBE has, therefore, been a benefit to the environment.

### PROPERTIES AND PRODUCTION

MTBE is a VOC that is produced by a chemical reaction of methanol and isobutylene. It was produced at chemical plants in very large quantities, more than 200,000 barrels (31,797,459 L) per day, in the United States alone in 1999. At room temperature, it is a volatile, colorless, and flammable liquid that evaporates quickly and is highly soluble in water. It was an ideal solution to the new strin-

gent requirements for gasoline because it blends well and is easily transported by pipeline or tanker to the refineries.

### RELEASE INTO THE ENVIRONMENT

MTBE has certain characteristics that make it a potent invader of the environment. It dissolves in water readily and does not adhere to organics in soil as many other compounds do. It is also thinner (less viscous) than many VOCs. As a result, when spilled, it can travel faster and farther than the other components of gasoline. It, therefore, reaches water wells and surface water well ahead of a gasoline plume and affects many more residences than does the plume itself. The problem can be especially acute near manufacturing, shipping, and pipeline facilities, although leaking tanks at gasoline stations provide more widespread distribution. MTBE does not degrade readily in groundwater systems, is resistant to bacterial action, and is very difficult and costly to remediate. This is not the case in surface water systems, where it has been shown to evaporate quickly. In the open air, it will break down to other compounds at a rate of one-half of the released volume in four hours.

### HEALTH EFFECTS FROM EXPOSURE

The first indication of health problems associated with MTBE occurred in 1992, when a spill in Fairbanks, Alaska, sickened residents. People complained of headaches, dizziness, eye irritation, burning sensation in the nose and throat, feelings of confusion, and nausea. MTBE is also used to dissolve gallstones in medical procedures. If it leaks into other parts of the body, it will produce the same temporary symptoms in addition to vomiting and a reduction in white blood cells. These would become the common symptoms of MTBE exposure. As a result of these health effects, extensive medical testing on laboratory animals was initiated. When exposed to high levels of liquid or vapor MTBE, some rats and mice died. Vapors further produced irritation to the nose and throat of animals, as well as disruption of the central nervous system. Animals acted as if they were intoxicated, with decreased activity, inability to stand up, and partially closed eyes. These symptoms dissipated within one hour. When animals were exposed to high concentrations of MTBE for extended periods, the symptoms were far more serious. Rats developed kidney disease and, in some cases, cancer of the kidneys. Some male rats developed testicular

cancer, and some female rats developed lymphoma and leukemia. Mice developed enlarged livers and in some cases tumors on the liver, and birth defects increased considerably.

### REGULATIONS ON HUMAN EXPOSURE

In 1997, the EPA concluded that at concentrations of 20–40 parts per billion (ppb) or below, MTBE was unlikely to cause any adverse health effects or even be detectable by taste. In 2000, in an effort to protect the health of children, the EPA issued recommendations that drinking water concentrations of MTBE should not exceed 4 milligrams per liter of water for exposures of one to 10 days and 3 milligrams per liter for longer exposures. In 2001, it became law that most public water supplies had to test for MTBE. The American Conference of Governmental Industrial Hygienists (ACGIH) recommends an exposure limit of 40 parts per million (ppm) of MTBE in air for an eight-hour-workday and a 40-hour workweek. The Energy Policy Act of 2005 removed the 2 percent oxygen requirements for reformulated gasoline and called for the phasing out of MTBE over the next nine years. Many states had already begun substituting ethanol for MTBE.

### CLEANUP OF MTBE

If soil and groundwater are contaminated with MTBE, there are several treatment alternatives. In soil, it is relatively easy to remove, because it is thin and does not adhere to organic particles. The treatment of choice is soil vapor extraction (SVE), which involves drawing air through the soil. The high vapor pressure of MTBE makes it easy to vacuum out. Removing MTBE from water is much more difficult. The standard procedure is to pump the water through granular activated carbon (GAC). The problem is that MTBE does not adhere to the activated carbon readily, so large quantities of water must be pumped through the system many times, and even then it may not all be removed. This procedure is costly and inefficient. Recent laboratory studies using genetically altered bacteria have yielded promising results. This may be the standard treatment in the future.

### Muir, John (1838–1914) Scottish-American

*Naturalist* John Muir was the first American environmentalist and is universally regarded as the grandfather of the movement. During a time when progress was the only interest of the vast majority of Americans, he asked that they think ahead and put aside natural wonders for future generations. The idea was so far ahead of its time that it took people by surprise. No one could even fathom that America would ever run out of natural resources or would have to consider protection of the environment. John Muir, however, had walked a great deal of the country and had seen the massive destruction. It was this vision of an America without wilderness that drove him to fight relentlessly for preservation. Through his writings and activism, he began slowly to turn America’s attention toward the environment. It was also primarily through his efforts that the Sierra Club and the U.S. National Park Service were established. These institutions have allowed a huge amount of land to be preserved in its natural state. Many of America’s natural treasures would have been gone without these efforts. The Sierra Club has also participated in significant pollution-reduction efforts. Were it not for John Muir, the environmental health of America would currently be much worse.

### BIOGRAPHICAL INFORMATION

John Muir was born on April 21, 1838, in Dunbar, East Lothian, Scotland. His parents were Daniel Muir and Ann Gilrye, and he was one of eight children. John entered school at the age of three but spent most of his free time fighting and hunting for birds' nests. In 1849, at age 11, John and his family emigrated to the United States and began a pioneer life near Portage, Wisconsin. Life was hard, but John was intent on schooling himself, so he slept a mere five hours a night to have time for his studies. He also made time to invent devices, primarily carved from wood with a pocket knife. He invented many ingenious devices that performed numerous functions including horse feeding devices, wooden clocks, and a thermometer made entirely from wood. In 1860, on the advice of friends, he traveled to the state agricultural fair in Madison, Wisconsin, to exhibit his inventions. His devices attracted so much attention that he was persuaded to enter the University of Wisconsin to continue his studies. He attended the university for five trimesters, or 2.5 years, and there he learned the basic sciences that he would use in his career. Although he had excellent grades, he did not graduate but instead chose to take a trek through Wisconsin, Iowa, Illinois, and part of Canada all by foot.

Muir returned to Indianapolis, Indiana, in 1866, and got a job making carriage parts. After a year at this position, however, he had an accident that temporarily blinded him in his right eye. This accident was a turning point in his life, because he decided that he could not risk never being able to see nature again. After he recuperated, Muir began a 1,000-mile (1,600-km) journey by foot from Indianapolis to the Gulf coast of Florida. From there, he sailed on a boat to Cuba and later to Panama, where he contracted a severe fever, possibly malaria. At that point, he decided to return to the United States and crossed the Isthmus of Panama and sailed up the west coast of Central America and Mexico, landing in California. He arrived in San Francisco penniless on March 28, 1868, and began walking again. He walked across the San Joachim Valley, saw the Sierra Nevada, and visited Yosemite for the first time. That would be his home from then on.

He began working in the area, first at a ranch, then as a sheepherder in the high Sierras, until he settled in Yosemite to operate a mill. Rather than simply using available technology, he put his ingenuity to work and designed a water-powered mill. He also began exploring the area and discovered glaciers in Yosemite. By studying locations and sedimentary deposits, he derived a controversial history for the area that was later confirmed by the famous geologist Louis

Agassiz. He also began writing during this time. Muir made enough of a reputation for himself that between 1871 and 1873 Ralph Waldo Emerson and other famous writers and naturalists sought him out. He was in the Owens Valley earthquake of March 1872 and wrote about the changes that had taken place as a result of the earthquake.

Muir's writing career began in earnest in 1874, when he left Yosemite to live in Oakland, California. He wrote a series of articles titled "Studies in the Sierra." His writings were not only about geology but also about ecology, including groves of giant Sequoias. To broaden his experience and expertise to other regions, Muir joined the U.S. Coast and Geodetic Survey in 1876. This position took him to many areas, including Alaska, where, in 1879, he discovered Glacier Bay and the glacier that would later bear his name. On April 14, 1880, at 42 years old, he married Louie Wanda Strentzel and moved to Martinez, California, where he and his wife raised two daughters. There, Muir entered a partnership with his father-in-law to manage the family fruit ranch in 1882 and, as usual, was very successful. Before the ranching period began, however, Muir was able to make one more trip to Alaska as a member of the Corwin Expedition in 1881. On this trip, he did extensive study of glacial formations and features, both along the Bering Sea and along the coast of Siberia.

After spending many years managing the ranch, building the Muir mansion, raising a family, and continuing his writings, John Muir began his excursions again with a trip to Mount Rainier. That year he edited a two-volume book titled *Picturesque California*. It was during this period that Muir began to become concerned about human encroachment on and destruction of his beloved wildlands. Although he had always been a scientist and naturalist, it was then that he became an activist. His main concentration was on preservation of the natural environment and the creation of a government institution to ensure it. He wrote a series of articles in 1889 urging the creation of a federal preserve around Yosemite, which took place the following year, when on September 30, 1890, Congress voted to make it a national park. Encouraged by this success, he pushed on and was the main force behind the creation of the Sierra Club on May 28, 1892, for which he served as president until his death in 1914. The first effort of the new club was to preserve the full size of Yosemite, which was under attack by logging and other groups that wanted to exploit the land rather than preserve it.

John Muir continued his excursions and scientific studies, but it was his activism and writing that took center stage and for which he is best known. He was personally involved in the creation

of national parks at Sequoia, Mount Rainier, Petrified Forest, and Grand Canyon, in addition to Yosemite. Muir fought for preservation of wildlands while others of his time fought for conservation, a less extreme philosophy, which resulted in a rift in this early environmental movement. Although some of Muir's excursions, such as a trip to Scandinavia in 1893, were motivated by personal interest, other excursions became more political. He was asked in 1899 to join the famous Harriman Expedition to Alaska because of his scientific and literary expertise, but he also befriended Harriman and later used his connection with him to apply pressure to Congress to pass additional preservation legislation. In 1901, Muir published his book *Our National Parks*, which caught the attention of President Theodore Roosevelt. In 1903, Roosevelt traveled to California to meet with Muir at Yosemite. It was there that Muir influenced Roosevelt's innovative and extensive conservation programs, including five national parks, 23 national monuments, and the preservation of 148 million acres (60 million ha) of national forest.

John Muir continued to write and travel but, in his later years, suffered several major setbacks. In 1906, the great San Francisco earthquake caused extensive damage to his house, which took time to repair. On August 6 of the same year, his wife of 26 years died. In 1907, he would become embroiled in a fight to save the Hetch Hetchy Valley above San Francisco. It was slated to be dammed to make a reservoir for the city, but Muir, referring to it as a second Yosemite, was adamant that it should be preserved for its beauty. The battle over it lasted six grueling years, and, ultimately, in 1913, the dam was built. Muir took a trip to South America and traveled 1,000 miles (1,600 km) up the Amazon basin, as well as an excursion to Africa in 1911 and 1912, at the age of 73. John Muir died of pneumonia on December 24, 1914, at the age of 76.

## HONORS AND AWARDS

During his career, John Muir was the author of 10 major books and more than 300 articles, 150 of which were in magazines and newspapers and designed to enlighten and persuade readers about conservation and preservation. As a result of his prolific writing and influence, John Muir was awarded an honorary degree of master of arts by Harvard University in 1896, an LL.D. degree by the University of California in 1896, an LL.D. degree by the University of Wisconsin in 1897, and a doctor of literature degree by Yale University in 1911. In addition to the Muir Glacier, there are two John Muir Trails (California and Tennessee), a John Muir Wilderness (California), and a Muir Woods National Monument (California). There are an asteroid named after him, an image of him on the California state quarter, and a John Muir Day on April 21 in California. Perhaps the greatest tribute to him was, in 1916, two years after his death, the establishment of the U.S. National Park Service, for which he had lobbied so forcefully.

# N

**naphthalene** Naphthalene is a very hazardous substance that is almost ubiquitous in everyday life. It is in all coal tar products from creosote and other wood preservatives to road tar and asphalt. It is released from coal burning and processing plants including power plants, coke ovens, metal smelters, and refineries, in addition to petroleum refineries. It is also released to the air from burning wood and tobacco. Even if it were only slightly toxic, it would still be dangerous by virtue of its dispersal. It is, however, toxic and therefore very dangerous. Naphthalene is also known as naphthalin, naphthaline, tar camphor, white tar, albocarbon, and naphthene. Naphthalene and its metabolites 1-methylnaphthalene and 2-methylnaphthalene have been identified in 654, 36, and 412, respectively, of the first 1,662 U.S. Environmental Protection Agency (EPA)–designated Superfund sites on the National Priority List where it was tested. Naphthalene was rated number 78 of the 275 most dangerous chemicals on the 2007 CERCLA Priority List of Hazardous Substances, and 2-methylnaphthalene was rated number 157 of 275. It is the physical and chemical properties of naphthalene that make it a health and environmental risk.

## PROPERTIES, USE, AND PRODUCTION

Naphthalene is a polycyclic aromatic hydrocarbon (PAH) that occurs naturally in petroleum and coal tar. In its pure state, it occurs as white scales, powder, balls, or cakes with a strong mothball odor. The 1-methylnaphthalene metabolite is a clear liquid, and 2-methylnaphthalene is also a white solid; they are similar in odor and other properties. Naphthalene is best known for its use in the production of mothballs, moth flakes, and toilet deodorant blocks. It is much

more commonly used in the production of chemicals and especially phthalic anhydrite, which is used to make plastics. Other uses include the production of pharmaceuticals, insect repellants and insecticides, leather tanning chemicals, dyes, synthetic resins, celluloid, lampblack, smokeless powder, solvents, lubricants, anthelmintics, and intestinal antiseptics. In 1999, 59 percent was consumed in the production of phthalic anhydrite, 21 percent in production of surfactants and dispersants, 11 percent in production of insecticide, and 9 percent in moth repellants and all other applications. It is no longer used in tanneries, in textiles, or in toilet bowl deodorizers.

Naphthalene was first isolated in 1819, but it was not named until 1821, and the chemical formula was not determined until 1826. Most naphthalene originates in coal tar, but from the 1960s to the 1990s, a large portion was derived from petroleum refining. Production of naphthalene in the United States peaked in 1968 at 900 million pounds (408,000 metric tons) but decreased into the 1990s to 222 million pounds (101,000 metric tons). Production has remained relatively steady in recent years, increasing slightly to 235 million pounds (107,000 metric tons) by 2000, 90 percent of which (219 million pounds [99,000 metric tons]) was from coal tar. Imports of naphthalene fluctuated in the United States in recent years, from a high of 40.9 million pounds (18.5 million kg) in 1989 to a low of 2.5 million pounds (1.1 million kg). In 2003, imports totaled 15.2 million pounds (6.9 million kg).

## ENVIRONMENTAL RELEASE AND FATE

Naphthalene is released to the environment as a point source pollutant from industry, transportation,

or storage; from spills or leaks; or from improper disposal. It is more commonly a nonpoint source pollutant, primarily from the residential burning of wood and fossil fuel, cigarette smoke, moth repellants and insecticides, and the degradation of wood preservative and road tar. When released into the air, naphthalene breaks down quickly by photolysis and reaction with hydroxyl radicals, typically within one day. When released into surface water, most naphthalene evaporates at the surface, but some dissolves, and it is commonly found in rivers and lakes. Subsurface removal results primarily from microbial activity and is complete within about two weeks. Once released into the soil, most naphthalene evaporates into the air, but that which remains is relatively mobile. It binds only weakly to soil and sediments depending upon their chemistry, allowing much of it to leach into groundwater systems. Naphthalene is removed from soil and groundwater primarily by biodegradation in about one to three months. It is not particularly persistent in the environment.

In the EPA Toxics Release Inventory (TRI) for 1998, the total release of naphthalene by industry to the environment was reported to be almost 6 million pounds (2,700 metric tons). By 2001, reported release had decreased to just over 2.6 million pounds (1,200 metric tons), of which more than 75 percent was released into the air. In 2005, the total release was back up to 3.82 million pounds (1.7 million kg). In 2006, the total off-site industrial release of naphthalene was 1,233,332 pounds (560,605 kg).

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects that result from exposure to naphthalene. Acute exposure produces neurotoxic effects, such as fatigue, confusion, lethargy, listlessness, loss of appetite, and vertigo, as well as gastrointestinal effects, such as nausea, vomiting, diarrhea, and blood in the urine. It also produces pale to yellow discoloration of the skin as well as skin and eye irritation and hemolytic anemia, a condition in which the red blood cells are damaged. People of Mediterranean and African heritage are especially susceptible to hemolytic anemia. Very high doses may result in death. Long-term, chronic exposure to naphthalene results in lung damage, cataracts, decreased body weight, damage to the lining of the nose, and kidney, liver, thymus, and spleen damage. Naphthalene can also cross the placenta in pregnant animals and cause fetal toxicity.

The U.S. Department of Health and Human Services classifies naphthalene as “reasonably anticipated to be a human carcinogen,” whereas the U.S. Environmental Protection Agency classifies it in group C—as a

possible human carcinogen—as does the International Agency for Research on Cancer (group 2B). Naphthalene has been shown to cause a rare but highly malignant cancer of the nasal passages that can spread to the brain in rats. It has also been shown to increase the incidence of lung tumors in some animals. Human epidemiological studies suggest that it could increase colorectal cancer and cancer of the larynx.

### REGULATIONS ON HUMAN EXPOSURE

Federal regulatory agencies limit exposure to naphthalene. The EPA recommends that naphthalene in drinking water be limited to 0.1 part per million (ppm) averaged over a lifetime of exposure and that children should not drink water with 0.5 ppm of naphthalene for more than 10 days or 0.4 ppm for more than seven years. They further require the reporting of environmental releases of 100 pounds (45.5 kg) or more of naphthalene to the National Response Center. The Occupational Safety and Health Administration (OSHA) lists a maximal permissible exposure limit (PEL) of 10 ppm in air for an eight-hour-workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) has set a recommended exposure limit (REL) of 10 ppm, a short-term exposure limit of 15 ppm, and an immediately dangerous to life and health (IDLH) limit of 250 ppm of naphthalene in air. NIOSH estimates that some 112,700 American workers were exposed to naphthalene from 1981 to 1983.

**National Zinc Bartlesville, Oklahoma (1991–2001) Soil Pollution** Zinc is an essential trace element or micronutrient for humans, animals, and plants and is included in most vitamin supplements. This minuscule amount plays a key role in the formation of hundreds of enzymes, regulating growth rates in children and young adults, and in immune system performance. As an industrial metal, zinc most often is mined as a coproduct with lead. Lead is used primarily in batteries and zinc in galvanizing. The excellent corrosion-resistant properties of zinc increase the service life of iron or steel in structural beams, roofing materials, and other objects exposed to weather. In galvanizing, steel objects are dipped into a vat of molten zinc and coated with a thin layer, usually 3 mils, or 0.003 inch (0.08 mm) thick. Zinc coatings are inexpensive, easy to apply, and maintenance free and can last for 40 years or more. About half the industrial demand for zinc is for galvanizing steel and other metals, but other applications include use as an alloying agent in metals such as brass and in chemical production. On an annual basis, a little more than 7.7 million tons (7 million metric tons) of zinc is extracted and processed from mines around the world.

The United States is the world's dominant producer of zinc, with 10 major mines in five states operated by seven companies. Mines in Alaska, Missouri, and Tennessee account for 97 percent of 770,000 tons (698,532 metric tons) of domestic production. Most U.S. production is from the Red Dog Mine in Alaska, but an important ongoing and historic source of zinc has been the area around the tristate mining district of Kansas, Missouri, and Oklahoma in the drainage basin of the Mississippi River. Within this region zinc and lead-bearing minerals of sphalerite and galena are part of sedimentary rocks. The ore bodies are contained in dolostone host rocks. These types of deposits are known generically as Mississippi Valley type, or MVT, ore bodies and account for 10–20 percent of the world's zinc

and lead mineral reserves. Mineralization is most often found in the open pore spaces of broken and crushed rock and as filling in fractures.

## INDUSTRIAL CONTAMINATION

In 1902, a company called Horseheads Industries, later National Zinc Corporation, began to exploit MVT zinc-lead deposits near Bartlesville, Oklahoma, about 45 miles (72.4 km) north of Tulsa. The first step used by National Zinc in refining its ore was to roast it to remove sulfur. It then was loaded into one of three horizontal retort zinc smelters that were in operation within or near Bartlesville. This process, developed by a Flemish priest in the mid-1800s, requires the use of numerous flask-shaped vessels. They are loaded with roasted or calcined zinc ore, typically about 1,000 pounds (454 kg); mixed with charcoal; and heated in a furnace. The zinc is driven off, or volatilized, and collected in a distillation vessel. Impurities such as lead, cadmium, and arsenic are also present in the gases, but in the past these gases were not collected or collected only periodically and most commonly were vented directly into the atmosphere. In the United States, Belgian furnaces of this type were built to hold 300–800 retorts. By the 1920s, two of the three horizontal retort smelters at National Zinc had ceased operation, and in 1976 the third smelter (which is now inactive) was converted to one using a more efficient electrolytic process.

Over the almost 70 years of zinc ore processing, the retorts operated without any or only minimal air pollution controls, and the metal-laden dusts and fumes that were emitted from the process vessels were discharged into the air around Bartlesville, eventually settling within an approximate three-mile (4.8-km) radius of the western side (downwind) of the National Zinc plant. These materials contaminated the soil and surface water with lead and, to a lesser extent, arsenic, cadmium, and zinc. In addition to air emissions, other sources of the metallic contaminants found in the Bartlesville environment (population about 40,000) include ore concentrates delivered to the facility by railcar, dust from the transport and storage of ore concentrates, and solid waste materials at the facility. The impacted area includes properties used for residential, commercial, industrial, recreational, and agricultural purposes. Wildlife habitat in undeveloped land is also present within the contaminated zone, and portions of the site are within the floodplain of the Caney River, the major surface water drainage system in the area.

In 1991 and again in 1992, responding to public concerns about the potential for lead exposure, the

Agency for Toxic Substances and Disease Registry (ATSDR), in cooperation with the Oklahoma State Department of Health (OSDH), collected blood samples from residents living both west and east of the National Zinc plant and analyzed them for lead levels. Findings indicated that approximately 14 percent of the children living to the west of the facility had blood lead levels greater than 10 micrograms per deciliter (mcg/dL). This is the concentration set by the Centers for Disease Control and Prevention as the indicator for potentially elevated blood lead levels. A control group of children, from areas of Bartlesville that are not in the vicinity of the site, had no incidence of blood lead levels exceeding 10 mcg/dL.

Children up to six years of age are the most sensitive to metal contamination in soil because during play and time outdoors, they tend to ingest soil. The concentrations of lead in soils downwind of National Zinc have been measured to be as much as 1.6 percent (16,000 mg/kg). These elevated concentrations presented an unacceptable risk of exposure that could result in developmental problems for children ranging in age from six months to six years. While not life threatening, these developmental problems could include learning disabilities, attention deficit disorder, and hearing loss.

Similarly, exposure to and accumulation of cadmium in the body can cause kidney damage and hypertension. Several studies also connect increased cadmium levels in the body to certain kinds of cancer. Concentrations of cadmium in soil downwind of National Zinc were present at up to 3.4 percent (34,000 mg/kg). Widespread elevated levels of arsenic were not found during site characterization studies, but the U.S. Environmental Protection Agency (EPA) established a goal for this contaminant during remediation in case it was found during cleanup efforts. A similar remedial goal for zinc was set because although zinc does not pose a significant threat to human health in most cases, it can damage sensitive ecological receptors at elevated levels, particularly in aquatic areas. High levels of zinc also can interfere with plant growth and result in damage to leaves and fruit.

### REMEDIATION EFFORTS

On the basis of these and other data, the EPA recommended the National Zinc property for inclusion as a Superfund site on the National Priorities List in 1993. Later that year, EPA directed the removal of contaminated soil in 25 residential “high-access areas,” including backyards, playgrounds, and schoolyards. Contaminated soil found in 10 more

nonresidential high-access areas also was removed. Using criteria developed as part of a site-specific risk assessment, the EPA established soil cleanup goals of 925 mg/kg for lead, 100 mg/kg for cadmium, and 60 mg/kg for arsenic.

There was a second round of soil removal in 1994. These efforts were focused on residential properties where at least one soil sample contained elevated concentrations of metals greater than 925 mg/kg of lead, 100 mg/kg of cadmium, or 60 mg/kg of arsenic. Once the contaminant was removed, the excavated area was refilled with clean soil and covered in sod. A third round of removal actions at impacted residential properties took place in 1995. The contaminated soil was isolated from the environment at commercial properties, by capping or covering it with clay, asphalt, or concrete, or by mixing the near-surface contaminated materials with deeper, underlying clean soil, and/or by adding phosphate to bind or chemically fix the metallic ions to the soil. Contamination that had made its way into the sediments of stream channels and local watercourses on the west side of the plant also was excavated. Excavated materials were shipped to a properly licensed off-site disposal facility.

In 1995, as remedial activities were being undertaken at National Zinc, ATSDR and OSDH reran the voluntary blood lead level testing program for children from infants to five-year-olds and repeated this testing annually until 2001. No elevated blood levels were reported in children from 1998 to 2001.

**Nevada Test Site Mercury, Mojave Desert, Nevada (1951–1992) Soil and Water Pollution**

The Nevada Test Site, or NTS, a 1,400-square-mile (3,584-km<sup>2</sup>) restricted access area, served as the United States' continental testing ground for the development of its nuclear weapons arsenal. Carved out of a larger tract of almost 5,500 square miles (14,245 km<sup>2</sup>) of unpopulated Mojave Desert, NTS also acts as a military gunnery range, is adjacent to the notorious Area 51 of UFO fame, and is used regularly as a massive outdoor laboratory and experimental center for everything from testing of hazardous spill response technologies to ecological habitat protection techniques.

There are 400 miles (644 km) of paved roads and 300 miles (483 km) of unpaved roads on the property, along with two airstrips capable of receiving jet aircraft, 10 heliports, an independent water supply, and electrical distribution systems. Along the south-central border of the site, the small town of

Mercury, Nevada, was established as a “base camp” and contains many of the facilities present in most municipalities such as housing, medical services, fire protection, a post office, law enforcement, and a restaurant. There are more than 1,100 buildings within NTS, including a fully equipped motor vehicle maintenance and repair shop.

### NUCLEAR TESTING

Beginning in 1951 and continuing until 1992, when the United States began to honor, although never officially ratifying, most of the articles of the Nuclear Test Ban Treaty, there were 925 nuclear tests at the Nevada Test Site. Of these, 100 were aboveground, or atmospheric, tests and 825 were belowground. Explosive yields ranged from 500 kilotons to one megaton, equivalent to the energy released by detonating 500,000 tons (454,000 metric tons) to 1 million tons (0.9 million metric tons) of trinitrotoluene

Craters from the detonation of nuclear bombs at the Nevada Test Site (U.S. Department of Energy/Photo Researchers, Inc.)

(TNT). Data from research and university seismographs collected during this period indicated that there also were numerous unannounced or secret tests.

In atmospheric, or aboveground, tests a nuclear explosive device was detonated while on the ground surface, on a steel tower, suspended from tethered balloons, dropped from an aircraft, or placed on a rocket. Underground tests took place by drilling a vertical shaft into bedrock, placing the nuclear explosive device inside the shaft, sealing the shaft with concrete, and then detonating the device. Approximately one-third of the more than 800 belowground devices were exploded near or below the water table. Underground testing was preferred because the explosive forces and fireball were more readily contained and the release of radioactivity to the atmosphere was minimized. In addition, underground testing allowed the placement of a much wider range of scientific measurement and experimental apparatus closer to the explosion.

Troops were stationed within a few miles of these explosions to allow the Defense Department to evaluate military preparedness in the event of wartime exposure to nuclear weapons and radioactive fallout. The NTS tests were performed only 65 miles (104.6 km) from Las Vegas. In the 1950s and 1960s, tourists traveled to the city to see the impressive mushroom-shaped clouds that were visible on the horizon.

### **POLLUTION AND REMEDIATION OF THE SITE**

A 1997 report by the National Cancer Institute later found that the atmospheric tests conducted at NTS between 1952 and 1957 resulted in the deposition of elevated levels of radioactive iodine 131 across most of the United States. Health effects from iodine and other radioactive isotopes released or created by these tests were concentrated in population centers downwind of NTS. As a result, in 1990, the U.S. Congress passed the Radiation Exposure Compensation Act, which established a fund to compensate nearby residents afflicted with certain types of illnesses that might have been caused by fallout from NTS testing activities. By 2006, almost 11,000 of these types of claims had been approved, and more than \$525 million in compensation had been awarded to NTS “downwinders.”

Currently, the U.S. Department of Energy (DOE) National Nuclear Security Administration Nevada Site Office is responsible for the management and operation of NTS. In cooperation with the state of Nevada, the DOE and Department of Defense (DOD) have conducted a series of investigations to

identify approximately 1,700 areas, called Corrective Action Sites and Correction Action Units (CASs and CAUs), where either surface or subsurface radiological contamination, including groundwater contamination, has been confirmed and delineated.

Of the confirmed 825 belowground nuclear tests carried out at NTS, approximately 275 were exploded near or below the water table. Contamination of groundwater has resulted in some areas of the NTS. These areas of known and potential groundwater contamination due to underground nuclear testing are called Underground Test Area (UGTA) CAUs. Approximately 57 million curies (Ci) of radioactive tritium remains belowground from the tests. A curie is the traditional measure of radioactivity: of 37 billion particles (disintegrations) given off every second. This is roughly equivalent to the radiation given off by 1 gram of radium 226. Curies have been replaced by the more widely used unit the becquerel, which is equal to one disintegration per second.

Tritium is a radioactive isotope of hydrogen that contains one proton and two neutrons; by contrast, standard hydrogen has one proton and one neutron. Tritium emits low-energy beta radiation that cannot penetrate skin. It is only harmful if inhaled or ingested. It readily combines with oxygen to form tritiated water, which is very mobile in the environment. Fortunately, as a result of tritium’s relatively short half-life of 12.3 years, if it can be contained for 123 years (10 half-lives), it does not represent a significant health risk.

Tritiated groundwater at NTS is found in six UGTA CAUs distributed along the northern and eastern sides of the site. Groundwater emanating from these UGTA CAUs generally flows to the south and southwest. In this area, the top of the water table is more than 500 feet (152.4 m) below the surface. There is no technology available for the cost-effective cleanup of this deep, extensive groundwater contamination. The NTS environmental monitoring program aggressively tracks the occurrence and movement of this contamination to help ensure that it will not affect downgradient groundwater users. The NTS remedial strategy for groundwater is to allow natural radioactive decay processes to operate and reduce the toxicity of the contamination. If an off-site groundwater user is threatened by the contamination, an alternate source of water will be provided. The tritium should decay to No Action levels by 2115.

More than 7 million cubic feet (203,914 m<sup>3</sup>) of contaminated surface soil containing radioactive americium 241; cesium 137; plutonium 238, 239, and 240; and strontium 90 has been detected at lev-

els in excess of 1,000 picocuries per gram (pCi/g) at 87 CASs on and around the NTS. These radioactive isotopes emit alpha, beta, and gamma radiation that, if inhaled or ingested, can result in cancer and other adverse health effects. Gamma radiation can penetrate skin and even certain types of metal shielding. The action level set by both DOE/DOD and the state of Nevada is 1,000 pCi/g, above which remediation or control measures become necessary to ensure an adequate level of protection for the public health. Soil cleanup levels at most other radiologically contaminated sites, those that are more accessible to the public or have a greater potential for the movement or migration of contaminants off-site, typically have action levels in the 3–50 pCi/g range. By 2007, three soil-contaminated CAS sites on NTTR were cleaned through excavation and removal. The remaining sites, both on and off the NTS property, are in the process of being remediated and restored.

### RESIDUAL RADIATION AND EXPOSURE

More than 80 percent of the ionizing radiation that people are exposed to in the United States is produced by natural sources. Ionizing radiation, which if emitted as unstable isotopes converts or decays to more stable atoms, consists of high-energy electromagnetic waves or particles that are capable of damaging cellular tissue.

Dosage is a measure of the amount of radiation a person receives. The higher the dose, the greater the amount of energy taken into the body and the larger the number of potential cellular molecules disrupted. A measure of the biologic risk of the energy received is the dose equivalent, and the units of dose equivalent are called rems, or, the more modern term, sieverts (Sv). One-thousandth of a rem is called a millirem, and in the United States, the average person receives about 300 mrem each year from natural sources and an additional 60 mrem from medical procedures, consumer products, and other activities.

It is not known whether there is a “safe” radiation dose equivalent, and most regulatory agencies take a conservative approach, assuming that there is no such thing as a 100 percent safe dose equivalent. They further assume that the risk of developing an adverse health effect, such as cancer, is proportional to the amount of the dose. Many human activities increase exposure to radiation above average background levels of 300 mrem/yr, and regulators balance the benefit of these activities to the risk of radiation exposure above background. The DOE has set the dose limit to the public from exposure to DOE-related nuclear activities to 100 mrem/yr (1 mSv/yr), which is the same public dose

### SOURCES OF RADIATION EXPOSURE

Source	Radiation
Five-hour jet plane ride	3 mrem
Building materials	4 mrem
Chest X-ray	8 mrem
Cosmic rays	30 mrem
Soil (naturally occurring isotopes)	35 mrem
Mammogram	138 mrem
Radon gas (from natural sources)	200 mrem
Computed tomography (CT) scan	2,500 mrem
Smoking (pack/day)	5,300 mrem (to lung)
Cancer treatment	5,000,000 mrem (to tumor)

Radiation sickness in humans occurs at short-term exposures of 100,000 mrem or more.

limit set by the U.S. Nuclear Regulatory Commission (NRC) and recommended by the International Commission on Radiological Protection and the National Commission on Radiological Protection and Measurements.

Although testing of nuclear weapons at NTS ceased in 1992, airborne radioactive contamination still occurs; it is due to the resuspension of contaminated dust and debris from areas where devices were detonated and from ongoing operation and maintenance activities such as waste management. Air quality within and along the boundaries of NTS is monitored continuously, and, since 1992, annual concentrations of airborne radiation have ranged from 48 to 2,000 Ci for tritium, 0.24 to 0.40 Ci for plutonium, and 0.39 to 0.49 Ci for americium. Surrounding communities typically have received radiation doses from NTS air emissions that are less than 1 percent of natural background, less than 3 mrem/yr.

In addition to soil, air, and groundwater, there are more than 1,600 sites containing pieces of large, discarded equipment that are contaminated by past nuclear testing activities. Over the past 10 years, the NTR environmental restoration program has been slowly and steadily decontaminating or safely disposing of the material at these sites, and only a few hundred remain. Remedial and other types of operational and maintenance activities have produced low-level radioactive waste (LLRW). In addition, historic NTS missions of research and testing

of nuclear-powered furnaces, rockets, and even airplanes have generated high volumes (thousands of cubic yards) of LLRW. These and similar materials taken to the site from other DOE facilities have been stabilized and permanently disposed of in two specially designed radioactive waste management areas on the site.

These disposal sites accept DOE LLRW from around the country, generated primarily by the cleanup of facilities where nuclear weapon components were manufactured and from DOD sites with a national security classification such as missile silos. LLRW is placed in unlined cells or trenches and covered with up to eight feet (2.46 m) of soil. For waste that may require more careful handling, a large-diameter borehole is drilled, into which drummed or specially boxed waste is placed. One area where LLRW is disposed of is within seven craters that make up five disposal cells. These craters were formed by underground weapons tests and are used for disposal of bulk LLRW waste including soil, debris, and waste in large cargo containers.

**New York City, air quality of New York, New York (1945–present) Air Pollution** In 1930, the population of New York City was 6.7 million, and by 1960 it had grown to more than 7.8

million, a 15 percent increase. In the 1940s through 1950s, New York State's \$25 billion economy, which accounted for almost 8 percent of the U.S. gross domestic product, had a robust and expanding industrial sector, one that provided high-paying employment in textiles, consumer products, and construction to World War II veterans returning from Europe and the Pacific. Along with the boroughs of Brooklyn, the Bronx, Queens, Manhattan, and Staten Island, the housing stock on Long Island and in the surrounding suburban areas was expanding quickly to accommodate the growing "baby boom," and New York City's public school system was widely regarded as one of the finest in the United States.

This type of rapid economic and population growth has an environmental price. In the case of New York City, it was air pollution. New York City's geography had helped it to avoid the air pollution disasters that had occurred in many other industrial and urban centers such as London; Donora, Pennsylvania; and the Meuse valley, Belgium. Much of the city lies within a few miles of Long Island Sound and the Atlantic Ocean, and the open, flat-lying topography, relatively evenly distributed annual precipitation, and prevailing westerly offshore breezes combined to dissipate the clouds of particulate and sulfur oxides that were the by-products of the coal and oil being burned in the city. Also helping to limit air pollution was an expanding mass transit system that kept thousands of cars off the roads on a daily basis.

#### POLLUTION OF THE AIR

But by the late 1940s and early 1950s, even these mitigating factors could no longer keep pace with the massive quantities of air pollutants being emitted across the metropolitan area. A series of dramatic air pollution events called the situation to the forefront of public attention, to the point that, by 1965, air pollution was a major issue in the mayoral election campaign of John Lindsay.

Between January 15 and January 24, 1953, a midwinter temperature inversion combined with an almost windless air mass allowed pollutant to climb to dangerously high levels. At the peak of the event, sulfur dioxide (SO<sub>2</sub>) levels were measured at 86 parts per million (ppm), whereas typical SO<sub>2</sub> concentrations were usually in the 0.15–0.20-ppm range. Current SO<sub>2</sub> emission levels are considered unhealthy above 0.14 ppm. The air also had a coefficient of haze, or COH, smoke shade value of 8.4. Usual COH values for New York City were less than 3. COH is a long-standing technique used to measure the concentration of large particulate matter based on its effect on the optical density of filter paper.

Although there are no national or state air quality standards for smoke shade, today a 24-hour average of 2.0 COH or greater is considered unhealthy for sensitive groups such as elderly people or those who have respiratory problems. During and shortly after this air pollution episode, which later articles in local newspapers described as “frightening,” the number of recorded deaths per day was 244, compared to the average of 226 deaths per day. The death rate from January 15 through January 24, 1953, increased across all age groups and over all causes.

A similar, although less severe event occurred between November 27 and December 4, 1962. SO<sub>2</sub> levels peaked at 0.7 ppm, with COH values in the range of 6.5. Several researchers attributed these more moderate pollution loads to the reduction in industrial and commercial activity associated with the long Thanksgiving Day weekend. Although there was no statistically significant increase in the city’s death rate, suggesting a threshold effect, a spike occurred on December 1, with 295 deaths compared to an average of 250.

Even as the intensity of the pollution events decreased, their frequency increased. The following table summarizes some of the more noteworthy air pollution episodes that occurred in New York City between late 1962 and early 1964.

Public health officials and academic researchers studying air quality in New York City during this period found that peaks in mortality rate generally matched peaks in air pollutant concentrations. They also found that these excess deaths were spread across the 45- to 64-year-old age group, as well as those older than 65 years old.

As in many American cities, coal played a major part in generating electricity and powering industry in New York City. World War II spurred the development and use of softer coals with higher sulfur content from West Virginia and Pennsylvania. With a better-coordinated and expanded rail system, this coal became the fuel of choice in the eastern United States. By 1950, New York City was importing and burning more than 27 million tons (24.5 million metric tons) of coal and more than 1.5 million gallons (5.7 million L) of oil. In addition, New York City relied heavily on the use of incinerators to manage its growing solid waste problem. The scarcity of suitable landfill space forced many apartment complexes, hospitals, and commercial buildings to burn their trash. These 30,000 incinerators were often poorly operated and maintained and consequently produced up to 40 percent of the SO<sub>2</sub> and particulate that fouled the city’s air, according to an estimate by New York City’s Department of Air Pollution Control.

Pollution overlying New York City, 2001 (Ray Stubblebine/Reuters/Landov)

### CLEANUP EFFORTS

In many respects, New York City’s attempts to improve its air quality were a reflection of similar efforts ongoing in Detroit, Cleveland, and Los Angeles. The sources of air pollution were well understood, including the burning of inexpensive, sulfur-rich coal and fuel oil, along with the widespread use of low-temperature incinerators. The political will to implement the necessary solutions, however, was not present.

Prior to World War II, air pollution control in the New York City metropolitan area was a mix of local, largely ineffective neighborhood campaigns focused on smoke-belching railroad locomotives or a particular industrial plant. During the war, air pollution control was ignored as all of the nation’s industrial might was brought to bear on producing the equipment and supplies needed to fight its enemies. After the war, attempts to introduce antismoke regulations in 1946, 1947, and much of 1948 that had meaningful penalties and attempts to create a Smoke Control Board within the Department of Housings and Buildings stalled because of only moderate public inter-

## AIR POLLUTION EPISODES BETWEEN 1962 AND 1964

Date	Description	Consequences
December 30, 1962–January 15, 1963	SO <sub>2</sub> —0.5 ppm COH—6	330 deaths recorded compared to an average of 270
January 29, 1963–February 13, 1963	SO <sub>2</sub> —0.7 ppm COH—7	330 deaths recorded compared to an average of 260
April 12, 1963–April 25, 1963	No reported increase in SO <sub>2</sub> or particulate values	temperature inversion occurred along with a slight increase in mortality
February 27, 1964–March 10, 1964	SO <sub>2</sub> —0.7 ppm COH—5	300 deaths recorded compared to an average of 260

<sup>a</sup> Cold temperatures (<20°F [-6.7°C]) and an outbreak of influenza may have contributed to the mortality rate during this period

est. Complaints soared during the heating season of October through March, when coal usage climbed and temperature inversions were more common, but declined sharply throughout the rest of the year. Intense lobbying of the mayor's office and city council by real estate and business and industry associations also stalled all efforts at control.

The October 1948 Donora, Pennsylvania, air pollution disaster changed the course of air pollution control. It clearly established the connection between air quality and public health in the minds of the American public including people in New York City. With some 20 people killed and more than a third of the town sickened, the Donora incident pushed air pollution control to the forefront of the political agenda. As a result, in February 1949, New York City had established a well-funded Smoke Control Board. By early August 1949, the board's 10 inspectors were trying to respond to more than 3,000 smoke complaints, most related to apartment building incinerators and boilers. Two of the more notorious smoke sources, Consolidated Edison Company (Con Ed) and the city's own Board of Transportation, refused to comply with Smoke Control Board inspection findings or even pay the fines levied against them.

Con Ed, the country's second largest utility company at the time, burned about half the soft coal in the region, and its Ravenswood and Hell's Gate generating stations were discharging more smoke than thousands of apartment buildings combined. The Board of Transportation operated its own coal-fired electrical generating stations to power the city subways, as well as operating thousands of old diesel-fueled buses. Requiring these facilities to be upgraded would cost millions of dollars and result in utility rate or fare increases. Similarly, forcing apart-

ment and commercial building owners to improve or replace antiquated incinerators or to switch to cleaner-burning natural gas would increase rents or even result in hated tax increases.

Faced with these and other political pressures, the Smoke Control Board, and its successor organization, Department of Air Pollution Control, began a 20-year program of community education combined with selective enforcement that attempted to cajole and pressure industry and the public into voluntary compliance with smoke abatement regulations. It proved to be only moderately successful. The city's air pollution control efforts ground to a halt, as both industries and real estate interests combined repeatedly to derail meaningful regulatory changes that would get at the heart of the problem, namely, the widespread use of inexpensive, dirty coal and the uncontrolled burning of municipal refuse.

By January 1967, New York City had the highest atmospheric sulfur dioxide concentrations in the United States. By that August, the federal government declared New York City's air to be the worst in the nation, with dangerously high levels of not only sulfur dioxide, but also carbon monoxide and particulate. One study predicted that the rate of pollution would make New York City "uninhabitable within a decade," and that residents might be required to live in domes or wear air-purifying respirators. These were not tongue-in-cheek suggestions, but dire warnings from respected government scientists. Adding to New York City's air pollution woes was the prevailing westerly breeze. Long an ally in helping to push particulate and sulfur dioxides out to sea, it now carried in smoke from heavily industrialized parts of northern New Jersey. The oil, chemical, and metal processing industries in Hudson, Bergen, and Essex Counties, as well as more

traditional sources of electrical generation and trash incineration, generated significant air pollution that was swept into the city. State and regional efforts to control pollution in New Jersey were even less effective than in New York, largely because of threats by many industries that they would leave the state if forced to implement expensive air pollution control programs. As a result, by 1965 an article in *Time* magazine described New Jersey's air as "hopelessly polluted."

Several half-hearted attempts were made by several states to organize and deal with air pollution on a regional level. For example, in 1967, Pennsylvania, New York, and New Jersey formed the Mid-Atlantic State Air Pollution Control Commission to establish and enforce air quality standards for all major pollution sources, but the commission never became operational, as a result of political squabbling among various state appointees. It had become painfully obvious that the economic and political pressures associated with forcing real change on urban coal usage, industrial emissions, and municipal trash incineration could not be overcome on a local level. By the mid-1960s, the federal government somewhat reluctantly stepped in to do what neither New York City nor many of the major cities around the country except, perhaps, Los Angeles was able to do: It sought to establish and enforce regulations that would help clear the nation's air. In 1970, shortly after the first Earth Day, the U.S. Congress passed the Clean Air Act Amendments, which gave the EPA primary responsibility for the control of air pollution.

Today, the air quality in New York City is much improved compared to that of the 1950s and 1960s. Air monitoring data for 2010 indicate that New York City meets federal National Air Quality Standards for carbon monoxide, nitrogen dioxide, sulfur oxides, and particulates. The city still does not regularly meet air quality standards for either ozone or, more recently, promulgated fine particulate (particulate matter with a diameter of 2.5 microns or less [PM 2.5]) standards. As improvements in mass transit and air pollution control technologies are made and as the regional economy continues to shift from industrial sector to a service base, within the next few years, New York City and its surrounding metropolitan region may soon have the best air quality of any large city in the nation.

**nickel** Nickel is a naturally occurring inorganic element that is categorized as one of the heavy metals. It is a group 10 metallic element and a transition metal and one of only five elements with ferromagnetic properties. It is the 24th most common element in the crust and believed to constitute more than 6 percent of the Earth's core, where it is most abundant. It occurs naturally in most rocks and soils and is emitted from volcanoes, as well as being a primary constituent of meteorites and ocean floor nodules. Human usage requires mining of nickel ore from either hard-rock sources, where minerals, such as aspentlandite and garnierite, are sought, or deeply weathered areas, where laterites are mined for soft minerals such as nickel-bearing limonite. The nickel ore is then either refined into pure metallic nickel or combined with other elements to produce nickel compounds. The compounds include nickel oxides and hydroxides, nickel sulfides, nickel salts, nickel carbonate, nickel carbonyl, and nickelocene, all with different properties and different uses. It has oxidation states of 0, +1, +2, +3, +4, and possibly +6. It is also considered by many to be a necessary human nutrient in very small quantities. In addition to its numerous beneficial industrial uses, nickel is among the more dangerous pollutants. It has been identified in 882 of the first 1,662 U.S. Environmental Protec-

tion Agency (EPA)–designated Superfund sites on the National Priority List. As the result of this wide distribution combined with the threat to public health, nickel was rated the number 51 worst environmental threat of the 275 top pollutants on the 2007 CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USES, AND PRODUCTION

There is evidence that nickel has been used by humans for some 5,500 years, largely as an addition to other metals to form alloys, typically to make them stronger, harder, more heat resistant, and less prone to deterioration. The first reported separation of nickel from other compounds occurred in 1751. Depending upon the compound, nickel is currently or recently used mainly for metallurgy and particularly in alloys such as stainless steel, as a chemical catalyst, in electroplating, in coins and jewelry, in nickel-cadmium and other long-life batteries, and in coloring glass. In 2002, 42 percent of nickel was used in stainless steel and iron alloy production, and 38 percent was used in nonferrous alloys and superalloys (mostly copper and silver), or approximately 80 percent of the total use. Of the remaining 20 percent, 14 percent was used in electroplating and 6 percent for all other uses. The ultimate uses of nickel in 2003 were 32 percent in transportation, 13 percent in the chemical industry, 10 percent in electrical equipment, 9 percent in construction, 8 percent in fabricated metal products, 7 percent in household uses, 6 percent in petroleum refining, 6 percent in machinery, and 9 percent in various other uses. Virtually all metallic nickel is used for metallurgy and electroplating, and the nickel compounds serve many of the other applications. Nickel oxide is used in alloys and steel but also in electronics, in fuel cell electrodes, in coloring of glass and ceramic, in nickel catalysts, and in manufacture of nickel salts. Nickel hydroxide is used in long-life, rechargeable batteries. Nickel sulfides are used as petroleum refining catalysts and some batteries. Nickel salts include nickel acetate and nickel chloride and are used in dyes, in electroplating, as catalysts, and in industrial gas masks. Nickel carbonate is used as a chemical intermediate, in pigments and dyes, in electroplating, and as a catalyst to remove contaminants from water. Nickel carbonyl is used to make high-purity nickel and in semiconductors, and nickelocene is used as a catalyst.

Nickel is primarily produced by Russia at 354,000 tons (322,000 metric tons) per year, Canada at 276,000 tons (258,000 metric tons) per year, Australia at 198,000 tons (180,000 metric tons) per year, and Indonesia at 159,000 tons (145,000 metric tons) per year, using 2007 statistics, although New

Caledonia, Brazil, and Cuba are also major producers. The largest single mine is in Sudbury, Ontario, which has traditionally produced about 30 percent of the world's supply. The United States has sizable deposits in Minnesota and had a steady production rate of 22 million–31 million pounds (10–14 million kg) per year from the mid-1950s through 1980. After 1980, mining declined significantly, and secondary recovery and recycling increased dramatically. Between 1980 and 1990, 55–83 million pounds (25–37.7 million kg) per year was produced from recycling, while primary production declined from 37 million pounds (16.8 million kg) in 1980 to 14 million pounds (6.4 million kg) in 1990. The last U.S. nickel mine closed in 1986, reopened in 1989, and closed again in 1998. Secondary nickel production was about 198–320 million pounds (90–145.5 million kg) per year between 1998 and 2002. Imports of nickel between 1970 and 2002 range between 220 million pounds (100 million kg) and 375 million pounds (170.5 million kg), with a generally increasing trend. In 2007, the United States imported 154,000 tons (140,000 metric tons) and consumed 254,000 tons (231,000 metric tons). The demand for nickel in the United States for stainless steel, nickel superalloys for aircraft and spacecraft, and rechargeable batteries is expected to continue to increase.

### ENVIRONMENTAL RELEASE AND FATE

Most Americans are exposed to small quantities of nickel, because it is widely distributed in air, water, food, and certain consumer products. In addition to natural sources, nickel is released to the environment during mining and refining operations and by the industries that produce nickel, nickel compounds, and nickel alloys or that use nickel and nickel products for manufacturing. It is also released by oil- and coal-burning power plants and incinerators. Nickel can enter the environment from smokestack emissions, industrial wastewater release, and dumping. Nickel entering the atmosphere may settle to the ground directly as fallout, be washed to the ground by precipitation, or attach itself to other particles and then settle to the ground. The duration of this process ranges from immediate to as much as several months. Most nickel is solid with some liquid, but nickel carbonyl can evaporate into an unstable vapor that breaks down quickly. In 1977–82, the concentration of nickel in urban air in the United States was 7–12 nanograms per cubic meter, but thanks to environmental efforts, it was reduced to an average of 2.2 nanograms per cubic meter by 1996. In soils, nickel and nickel compounds tend to bind tightly

to particles that contain iron or manganese and are relatively immobile. They average 4–80 parts per million (ppm) in soil but have been found as high as 9,000 ppm near smelters. Besides some nickel salts, virtually all nickel and nickel compounds are insoluble in water, but metallic nickel, nickel oxides and hydroxides, nickel carbonate, and nickel carbonyl are soluble in certain acids. In conditions of acidic soils, they may become mobile and enter the groundwater system. Nickel in wastewater typically attaches to particles and settles into the sediment. In most surface water systems, nickel averages less than 10 parts per billion (ppb), and in drinking water it ranges from 2 to 4.3 ppb in the United States. It is estimated that 27 million pounds (12.3 million kg) of nickel was released into the environment between 1987 and 1993. The states with the largest releases are, in order, Oregon, Arizona, Idaho, Indiana, Pennsylvania, Arizona, Texas, Maryland, California, and Georgia.

### TOXICOLOGY AND HEALTH EFFECTS FROM EXPOSURE

Nickel and nickel compound exposure produces numerous adverse health effects. The most common health effect in humans is allergic reaction. About 10–20 percent of people are sensitive to nickel and develop skin rashes, dermatitis, and, less commonly, asthma attacks. People may develop sensitivity through chronic long-term exposure. Acute short-term exposure may produce headache, nausea, respiratory problems, kidney damage, increased red blood cells, and death. Soluble nickel compounds are more toxic than insoluble compounds, and nickel carbonyl is extremely toxic through inhalation by producing carbon monoxide gas. Long-term chronic exposure has produced chronic bronchitis; reduced lung function; kidney, liver, and blood disorders; immune system damage; possible reproductive effects; and cancer. Nickel compounds are classified as known human carcinogens (group A), and metallic nickel is classified as reasonably anticipated to be a human carcinogen (group B2). It has been shown that human exposure to nickel compounds increases lung and nasal cancer. Cigarette smoking has a multiplicative effect. It has also been shown that exposure to both nickel and nickel compounds can cause cancerous growths in numerous sites and numerous species of laboratory animals. These include lung, kidney, liver, pulmonary, and pituitary cancers in exposed animals and kidney, liver, and spleen cancer in their offspring. Cancers also developed at every site of injection of nickel compounds. Nickel exposure may also cause genetic damage. Human and

rodent cell cultures exposed to nickel compounds showed deoxyribonucleic acid (DNA) strand breaks, mutations, chromosomal damage, cell transformation, and disrupted DNA.

### REGULATIONS ON HUMAN EXPOSURE

Federal regulatory agencies limit exposure to nickel and nickel compounds. The USEPA limits the amount of nickel in drinking water to 0.1 milligram per liter and requires the reporting of environmental releases of 10 pounds (4.5 kg) or more of nickel carbonyl, nickel cyanide, and nickel hydroxide and 100 pounds (45.5 kg) or more of metallic nickel and all other nickel compounds. The Occupational Safety and Health Administration (OSHA) lists a maximal permissible exposure limit (PEL) of 0.007 milligram per cubic meter of air for nickel carbonyl and 1 milligram per cubic meter of air for metallic nickel and all other nickel compounds. The National Institute of Occupational Safety and Health (NIOSH) has set a recommended exposure limit (REL) of 0.001 ppm for nickel carbonyl and 0.015 milligram per cubic meter of air for metallic nickel and all other nickel compounds. Their immediately dangerous to life and health (IDLH) limit is 2 ppm of nickel carbonyl and 10 milligrams per cubic meter of air for metallic nickel and all other nickel compounds. NIOSH estimates that some 507,681 workers were exposed to nickel and nickel compounds from 1981 to 1983.

### **Norilsk mine and smelter** *Norilsk, Siberia, Russia (1950–present)* *Air and Water Pollution*

Norilsk is a city located just above the Arctic Circle in Siberia, Russia. In winter, temperatures can reach  $-76^{\circ}\text{F}$  ( $-60^{\circ}\text{C}$ ), and yet some 130,000 residents live there. The reason that it is so populated is that Norilsk was built to exploit some of the richest deposits of nickel, copper, palladium, and platinum in the world. The rocks in the area are 250-million-year-old lava flows, collectively called the Siberian Traps. These lavas were rich in sulfur, which combined with nickel, copper, and other metallic elements to form concentrated deposits of pentlandite ( $[(\text{Fe}, \text{Ni})_9\text{S}_8]$ ), chalcopyrite ( $\text{CuFeS}_2$ ), and other ore-bearing minerals. Estimated reserves for these valuable industrial minerals are almost 2 billion tons (1.8 billion metric tons). Ores are removed from underground workings that extend more than 3,900 feet (1,200 m) belowground. The presence of these deposits had been known for many years, but large-scale mining operations did not begin until around 1935, just before the start of World War II. Norilsk was developed and settled in the 1920s and 1930s, primarily by political prisoners and slave laborers exiled to Siberia from other parts of the Soviet Union, although a substantial number of volunteers also moved north to seek employment in the mines and metal processing plants. The city quickly became the regional center for the refining and smelting of ore removed from the surrounding mines. A rail line was extended southward to ports on the Yenisei River, where, during the summer, refined metal and processed ore were transported to the rest of Russia by sea.

For the next 50 years, the Norilsk Metallurgical Combine, a government-owned and operated company, ruthlessly extracted and refined copper, nickel, platinum, and other metallic ores from around Norilsk, without regard to either the environment or the health of its residents. When the Soviet Union broke up in 1995, the Norilsk Metallurgical Combine was privatized through purchase from the government by political insiders for \$150

million and renamed the Mining and Metallurgical Company Norilsk Nickel, or more simply Norilsk Nickel. The new company also maintained its policies of environmental indifference. The company, one of the world's largest miners, generates more than 4 percent of Russia's exports. It is the world's largest producer of nickel and palladium and has major interests in other gold, cobalt, and platinum operations.

The need to attract the \$1 billion of outside investment essential to modernize the aging infrastructure, as well as to meet European Union environmental standards, is forcing mining company and city officials to address three basic challenges to the region's survival: the rehabilitation of the environment, the healing of its citizenry, and the sustainability of its economy.

### **EMISSION OF POLLUTANTS**

After the ore has been removed from the ground and separated from the gangue, or nontarget, minerals, the copper and nickel must be separated from the other elements in the ore minerals. This is done by first calcining, or cooking, and then smelting the ore. The ore is heated in huge vats with other rocks or minerals until everything is molten. There chemical reactions take place in which the elements other than copper or nickel present in the ore minerals are removed into other compounds. The heavier metals settle to the bottom, where they are collected. The lighter compounds float to the top of the molten mass and are skimmed off as slag and discarded. Smelting is energy intensive, but fortunately coal is abundant near Norilsk, and the smelters can be fired using this cheap, plentiful fuel. The problem is that the by-products of both smelting and mining have a high environmental price. During smelting, sulfur in the ore combines with oxygen in the atmosphere to form sulfur dioxide and other sulfur compounds that are released to the atmosphere as vapors. Metals are also released to the atmosphere in this process. Once in the air, the sulfur compounds mix with water vapor to create acid rain. More sulfur, as well as particulate and other dangerous elements such as mercury, is released during the burning of the coal used to heat the ore and power the mills and furnaces. Finally, slag and unprocessed waste rock are dumped in large uncontrolled piles or settling ponds, where they leach metals into soil, surface water, and groundwater. A roughly 25-mile (40-km) area around Norilsk is ecologically dead. All the trees and other vegetation have

(opposite page) Nickel refinery in Norilsk, Russia, dumps tons of sulfur dioxin into the atmosphere every year. (Oleg Nikishin/Getty Images)

been killed by acid rain, and the landscape is scarred by large open pits and piles of waste rock and debris. In some places the upper few feet of soil is so heavily contaminated by atmospheric fallout of nickel and copper that it is economical to mine.

Almost 15 percent of all the industrial pollution in Russia is produced by Norilsk Nickel, with its main Nadezhda Metallurgical facility emitting more than 2 million tons (1.8 million metric tons) of sulfur dioxide into the atmosphere every year since 1950. For comparison, sulfur dioxide emission from all industrial and commercial activities within the entire United States, including electrical generation, is about 15 million tons (13.6 million metric tons) per year. The smelters in Norilsk are arguably the major source of air pollution on the planet. The sulfur and dust stain the snow yellow and black, and the air often tastes sour. Residents have nicknamed the city “Frozen Hell” or “Hell with a Lid On.”

In addition to air pollution, wastewater used in ore processing and metal finishing is discharged without treatment into local watercourses and has resulted in the contamination of more than 60 miles (100 km) of streams and rivers. Although records are difficult to obtain and verify, some environmental advocacy groups have estimated that more than 500 million gallons (1,893 million L) of unprocessed industrial sewage is discharged every year from Norilsk smelters and mines into the rivers and streams of the sensitive Siberian ecology.

There are signs that environmental controls are being slowly implemented at Norilsk. Since 1984, the total amount of air pollution has started to decline very slowly, although levels are still thousands of times above the standards of most Western countries. Plant managers have sought and received outside advice on controlling air pollution, particularly from a Finnish mining and mineral company named Outokumpu Oy. Although severely damaged, the local ecology can recover over time, once the sources of pollution have ended or are under control.

### **PUBLIC HEALTH EFFECTS FROM EXPOSURE**

The environmental consequences of mining and metal processing in Norilsk are highly visible, but the impacts of the operations on the health of its residents are less apparent. Government public health data are not readily available, but even Norilsk Nickel officials admit that only about 4 percent of all adults in the city are “healthy.” Children are particularly affected by the severe air pollution, with skin rashes and respiratory problems, particularly asthma. The air is so polluted that children must be kept indoors 90 days per year.

Company workers can retire at 45, but few live long enough to collect much of a pension. Some published studies have found that living in Norilsk will lower an average person’s life span by 10 years. Although many factors contribute to the poor state of public health in Norilsk, including rampant alcoholism, little to no exercise, and harmful dietary habits, there seems no doubt that the poor quality of the air, water, and environment in general is a significant contributor to the general ill health of the population.

### **ECONOMIC PRESSURES ON MINING**

After the last forced labor camps and gulags closed in the 1970s, many of Norilsk’s current residents were lured to the city by promises of higher salaries, free vacations, and early retirement. Wages in Norilsk are generous by Russian standards, up to \$700 per month, compared to a national average of around \$300 per month. Few workers, however, can afford to leave. The isolation, expense of relocation, difficulty in obtaining housing, and inability to find equivalent employment in other parts of Russia all combine to maintain a captive workforce.

After the collapse of the Soviet Union and the transition to a market-driven economy, the guaranteed employment and pensions the residents of Norilsk learned to expect began to disappear. To remain competitive, the labor force was slashed by almost half (from 100,000 to 60,000), and there are plans to relocate more than 100,000 people living in Norilsk to other parts of Russia. The city simply cannot sustain itself at its current population level. Without major subsidies from the Russian government, it is too expensive to operate the city, and the cost of importing food and other supplies is too high to be economically viable.

One measurable sign of the economic hardships that Norilsk residents are facing is seen in its animal control problem. Attacks on people by stray dogs have become commonplace. As economic conditions changed, many people could no longer afford to keep their pets. As a result, they were abandoned. The number of abandoned and stray dogs in Norilsk has increased significantly, and they are becoming more and more aggressive, forming packs that regularly attack people.

Norilsk is typical of many such Russian towns and communities. A 2000 government-sponsored environmental survey identified 120 cities in Russia that have air quality up to five times worse than acceptable health levels. Even with a major infusion of financial and technical resources from outside the country, Russian environmental quality is not likely to improve over the foreseeable future, as long as

the means of production are driven solely by market factors and remain unchecked by an immature and mostly ineffective regulatory culture.

**Nowruz Oil Field Persian Gulf, Iran (1981–1988)** *Water Pollution* The Middle East holds about two-thirds of the planet's oil and gas reserves. It is for this reason that it has become so hotly contested over the last quarter of the 20th century and entire 21st century. At some point in the future, historians may refer to the multitude of military conflicts that have erupted there as "the energy wars." Direct attacks on oil production facilities are common in conflicts, as is the disruption of supplies. The largest environmental discharge of oil ever in history occurred in the 1990 Desert Storm conflict, in which retreating Iraqi military forces blew up more than 80 percent of the wellheads in Kuwait's oil fields. The area may never recover ecologically from this disaster. Nowruz is nowhere near as immense as this, but it still played an important role as a strategic piece in the Middle East conflicts.

### BACKGROUND

Some 400 million years ago, as sea level rose, a broad stable platform formed over the Middle East

region. The area changed over time to include a thick salt layer, as well as the deposition of sands, shale, and limestone at various times. Later, these strata were folded, faulted, and intruded by salt domes that accumulated vast quantities of hydrocarbons. Within the Persian Gulf, the reservoir rocks that contain the oil and gas are often in patterns of closely spaced, interconnected fractures in limestone or shale or even in sandstones and coarse-grained sedimentary rocks closer to the surface. The fields are most commonly in broad anticlines and salt domes that contain enormous reserves.

Just after the turn of the 20th century, the first commercial quantities of oil were discovered in Iran. By 1911, the British-owned Anglo-Persian Oil Company (APOC) had developed fields and were shipping the oil by tankers to Europe. After World War I ended, oil was found in Iraq, and by the early 1930s, Standard Oil Company of California (SoCal) was producing oil from fields in Bahrain and Saudi Arabia. By the 1950s, tiny Kuwait had emerged as the region's biggest oil producer, in large part as a result of a government that cooperated enthusiastically with both foreign technical and financial experts. Oman, Qatar, and Abu Dhabi became very active exporters of oil by the early 1960s. By the 1970s, many Persian Gulf countries had taken over active management of the companies producing oil within their borders, and by the 1990s most of these once foreign-controlled corporations were wholly government owned.

Of the Persian Gulf countries, Iran's economy in particular relies extensively on revenues from the export of oil. Western experts estimated that approximately 80 percent of Iran's export earnings are oil related and that oil revenues account for about 50 percent of this country's annual operating budget. In 2004, Iran's oil export revenues were estimated at \$32 billion. By 2005, they were more than \$45 billion and grew to almost \$50 billion in 2006. With this much money at stake, money needed to provide for its people, many of whom are desperately poor, it is no wonder that Iran named one of its most productive oil fields, lying just 40 miles (64 km) off of its coastline, Nowruz.

In Iran, Nowruz is one of the most widely celebrated nonreligious, or secular, holidays. It is the first day of spring or vernal equinox and the beginning of the traditional Iranian New Year. Usually the celebration, also called the Eid Festival, takes place around March 21. Many other countries in addition to Iran celebrate Nowruz, or the "rebirth of nature," including peoples in northern Iraq, Turkey, Afghanistan, and several countries of Central Asia.

### THE POLLUTION

In the early 1980s, a series of pollution events focused the attention of the Arab world on the Nowruz oil field. Iran and its neighbor Iraq went to war in September 1980 because of a long-standing dispute over the control of a key river, the Shatt al Arab. This 120-mile- (193-km-) long tidal stream, formed by the confluence of the Tigris and Euphrates, empties into the Persian Gulf and provides key access to it. It also forms a portion of the boundary between these two countries.

The problems at Nowruz began in 1981, when an out-of-control tanker collided with one of the oil platforms that were actively extracting oil. A well that was damaged beyond easy repair in the accident was successfully capped. Two years later, on February 4, 1983, the platform that the wellhead was attached to began tilting at a precipitous angle. Buffeted by high winds and strong waves, combined with unnoticed corrosion, the riser pipe eventually collapsed into the wellhead. The riser is the part of the pipe that extends above the seafloor and is attached to the wellhead, the point where the borehole enters the seafloor. This collapse began to release approximately 1,500 barrels of oil per day

(almost 60,000 gallons [228,000 L]), and it had to be sealed quickly to prevent a major environmental catastrophe.

When American well-capping experts hired by Iran to seal the blowout asked Iraq for safe passage to the platform, Iraq responded by having its helicopter gunships attack seven other Iranian wells in the same area. Although safety valves automatically shut down four of the damaged wells, the other three began leaking oil into the Persian Gulf at a rate of about 30,000 barrels (1,200,000 gallons, or 4,560,000 L) per day. The resulting slick that formed near the wellhead caught fire, and the oil bubbling to the surface eventually spread to cover 9,000 square miles (23,040 km<sup>2</sup>), or almost 10 percent of the Persian Gulf's open water surface area. Approximately 700,000 barrels (28 million gallons, or 106 million L) of oil spilled into the gulf from these intentionally damaged wells. By mid-May 1983, between 4,000 and 10,000 barrels (160,000–400,000 gallons, or 608,000–1.52 million L) of oil per day was still being released.

As the oil spread, it began to threaten hydrocarbon extraction and recovery operations at not only other platforms and fields, but also other parts of the

Dugong in Lamen Bay, Epi Island, Vanuatu (Mike Parry/Minden Pictures)

industrial and commercial infrastructure that many countries had built up around the waters of the Persian Gulf. These facilities included desalination plants; cooling water intakes for power plants, ports, and harbors; as well as fisheries and habitat for both commercial and indigenous species of plants and animals. The entire population of Persian Gulf sea cows, or dugongs (*Dugong dugon*), was wiped out. These 11-foot- (3.4-m-) long, 2,000-pound (909-kg) creatures, similar to Florida's manatees, use their pointed flippers to "walk" along the seabed as they feed on sea grass, algae that grow in shallow marine environments such as bays, channels, and inshore islands. Although inhibited by the ongoing hostilities from making complete studies, scientists also estimated that large numbers of dolphins, turtles, sea snakes, and birds were killed as the massive slick began to wash ashore on beaches along the gulf. The Nowruz field oil is a "heavy" crude oil, with an American Petroleum Industry (API) gravity of 22. Although information on how the oil behaved once released into the gulf is not available, an estimated 60 percent is thought to have sunk to the seafloor as tarballs, after sand carried by high winds mixed with the oil.

The Iranians successfully shut off the flow of oil from the initial blowout on September 18, 1983. Eleven people died during the operation. In May 1985, the United Nations negotiated a fragile cease-fire between Iraq and Iran that held long enough to allow the fire to be extinguished and three other Nowruz wells to be capped. Nine workers were killed during those operations. The wells leaked more than 30 million gallons (114 million L) of oil into the Persian Gulf over a period of more than two years. The cease-fire did not hold long, and on August 15, 1985, Iraq again attacked the Nowruz oil field. Iraq also launched an air assault, the first of more than 40, on Kharg Island, Iran's main oil export terminal.

Kharg Island is a small island (about 10 square miles, or 26 km<sup>2</sup>) in the northern Persian Gulf. Despite its diminutive size, this island plays a large strategic role in the development of oil resources in the northern gulf. About 16 miles (25.6 km) off the Iranian coast, Kharg Island extends Iran's claim to oil reserves farther into the gulf oil fields. More importantly, Kharg Island has been developed (initially by Amoco in a joint venture with Iran's National Petrochemical Company [NPC]) into one of the largest oil storage and processing terminals in the gulf. Now operated solely by NPC, the Kharg Island terminal processes, stores, and exports more than 90 percent of Iran's oil. Oil from offshore platforms is pumped via pipeline into the

terminal's storage tanks, where it is processed to remove methane, water, and salt. The oil then is loaded onto tankers for shipment through the Straits of Hormuz for delivery in Europe, the Americas, and Asia. The Kharg Island complex was rebuilt after the Iran-Iraq War, which ended on August 20, 1988. It was expanded in 1994 to increase its capacity by more than 40 percent. The dispute over the Shatt al Arab was finally settled when a coalition of international military forces, led by U.S. and British troops, invaded Iraq in 2003.

**NO<sub>x</sub> (oxides of nitrogen)** The U.S. Environmental Protection Agency (EPA) began tracking emissions of the six designated principal air pollutants in 1970. By 1998, levels of five of the six, carbon monoxide, lead, particulate matter, sulfur dioxide, and volatile organic compounds, had all been substantially reduced, but that of NO<sub>x</sub> had actually increased 10 percent over the period. Considering that NO<sub>x</sub> is a direct cause of ground-level ozone (smog), acid rain, surface water quality deterioration, global warming, decreased visibility, toxic chemical production, and the production of particulate matter, it is a great threat to the environment, as well as human health. Since 1998, efforts have been stepped up to reduce NO<sub>x</sub>. There are several oxides of nitrogen (components of NO<sub>x</sub>) including nitric oxide (NO, or nitrogen I oxide), nitrogen dioxide (NO<sub>2</sub>), dinitrogen monoxide (N<sub>2</sub>O, or nitrous oxide), dinitrogen trioxide (N<sub>2</sub>O<sub>3</sub>, or nitrogen III oxide), dinitrogen tetroxide (N<sub>2</sub>O<sub>4</sub>), and dinitrogen pentoxide (N<sub>2</sub>O<sub>5</sub>). Nitric oxide is undesirable, and nitrogen dioxide and dinitrogen monoxide are toxic; the other three are unstable. NO<sub>x</sub> is so widespread and affects so many people in so many ways that it is one of the most hazardous pollutants.

Nitrogen dioxide has been identified in nine of the first 1,585 EPA-designated Superfund sites on the National Priority List, and nitric oxide has been identified in six. On the 2007 CERCLA Priority List of Hazardous Substances, nitrite is ranked as the 212th worst pollutant, and nitrate is 216th of 275 substances listed.

### PROPERTIES AND SOURCES

Nitrogen dioxide is a colorless to brownish liquid with a sharp harsh odor at room temperature but a red-brown gas above 70°F (21°C). Nitric oxide is a colorless, sharp, but sweet-smelling gas. There was about 58 million tons (53 million metric tons) of NO<sub>x</sub> released into the atmosphere by human activity on a global basis in 1970. The total natural and

anthropogenic releases of NO<sub>x</sub> were 1.2 billion tons (1.1 billion metric tons), an indication that natural sources predominate by nearly 95 percent. Natural sources include bacterial action on soil, volcanic eruptions, forest fires, and lightning. Natural NO<sub>x</sub> is spread evenly throughout the atmosphere, whereas anthropogenic NO<sub>x</sub> is concentrated at the sources, building to dangerous levels on a local scale. The anthropogenic sources of NO<sub>x</sub> emissions in the United States in 2003 were 55 percent from motor vehicles; 22 percent from utilities, including power generation; 22 percent from industrial, residential, and commercial sources; and 1 percent from all other sources. The commercial sources include arc welding, electroplating, engraving, dynamite blasting, and the production of numerous chemicals, dyes, lacquers, rocket fuel, trinitrotoluene (TNT),

**Schematic diagram showing the steps in producing NO<sub>2</sub> from car exhaust and the three main hazards in the atmosphere that it leads to: ozone, acid rain precipitation, and nitrates**

gun cotton, and dynamite. Nitrous oxide is also used for dental anesthesia (laughing gas). Scientific studies in 2005 showed that up to 9.7 million tons (8.9 million metric tons), or 22 percent of NO<sub>x</sub>, is directly emitted to the atmosphere from nitrogen-fertilized (ammonium and nitrate) farmland, a total much higher than previous estimates. NO<sub>x</sub> is also produced in tobacco smoke, where typical concentrations are 145–230 parts per million (ppm), well into toxic levels.

It is estimated that 25 percent of NO<sub>x</sub> emissions were from coal-fired power plants by 2006. NO<sub>x</sub> is produced from coal by several processes including (1) fuel NO<sub>x</sub> by direct release through burning; (2) thermal NO<sub>x</sub> by the splitting of stable nitrogen atoms by high temperatures, which then react with oxygen; (3) prompt NO<sub>x</sub> from the reaction of atmospheric nitrogen with radicals; and (4) feed NO<sub>x</sub> from cement production, the last two of which are negligible.

### ENVIRONMENTAL INTERACTIONS

NO<sub>x</sub> is primarily a nonpoint source pollutant that is released to the atmosphere. It occurs rarely as a point source pollutant in waste sites. When released to the atmosphere, NO<sub>x</sub> degrades rapidly in air by reacting with other chemicals. Most NO<sub>x</sub> rapidly oxidizes to nitrogen dioxide (half-life of about 50 days depending upon conditions). Nitrogen dioxide reacts with photochemically produced radicals to form nitric acid, which is a major component of acid rain. It also reacts photochemically with volatile organic compounds to form ozone or smog, which accounts for much of the regional haze in urban and even rural areas. The average annual visibility in the Great Smoky Mountains is reduced to 25 percent by fog. Much of this NO<sub>x</sub> is returned to the surface in precipitation as acid rain, which damages vegetation and helps to produce the “dead lakes” of the Adirondack Mountains and other areas. In water bodies where the pH is buffered to near-neutral conditions, the increased nitrogen causes *eutrophication*, or oxygen depletion by algal blooms. Coastal waters are especially susceptible to nitrogen fallout and washout. It is estimated that deposition of air pollution-generated nitrogen accounts for 33 percent of the total nitrogen load in the Albemarle-Pamlico estuary of North Carolina, 27 percent of that in the Chesapeake Bay of Maryland and Virginia, and 15 percent of that in the Long Island Sound, New York.

NO<sub>x</sub> has daily and seasonal trends in urban and suburban areas. There are typically two times of high concentrations during the day, corresponding to morning and evening rush hour. During these

times levels can be twice as high as they are during the lowest periods of the day. The highest concentrations in the atmosphere are typically the winter months of November through February, whereas the lowest months are the summer months of June through August. The reason for this is that NO<sub>x</sub> reacts with volatile organic components to produce ozone if exposed to strong sunlight. The summer reduction corresponds to a sharp increase in ozone, which is also toxic and destructive.

NO<sub>x</sub> additionally contributes to the level of particulate in the atmosphere. Through reactions with water vapor, ammonia, and other compounds, NO<sub>x</sub> helps to form small particles that can cause respiratory system damage. People with asthma, heart disease, emphysema, and other respiratory problems are especially sensitive to particulate. These reactions may also produce toxic chemicals that may damage vegetation and human and animal health if inhaled. NO<sub>x</sub> is also a greenhouse gas and, therefore, contributes to global warming.

If it is released directly into water, a small amount may evaporate, but the majority of the NO<sub>x</sub> will react with the water to form nitric acid. If it is released into the soil, small amounts may evaporate into the air, but the majority will react to form nitric acid. Animals (birds and mammals) experience similar adverse health effects to exposure to NO<sub>x</sub> that humans do, and plants may also be damaged.

### HEALTH EFFECTS FROM EXPOSURE

Exposure to NO<sub>x</sub> can cause numerous adverse health effects. Acute exposure to low levels of NO<sub>x</sub> can irritate the eyes, nose, throat, and lungs and produce coughing, shortness of breath, fatigue, nausea, and vomiting. Within one to two days of no symptoms after the initial exposure and effects, fluid may build up in the lungs from pulmonary edema and may be accompanied by anxiety, mental confusion, lethargy, and loss of consciousness. Exposure to high levels of NO<sub>x</sub> can cause rapid burning, spasms, and swelling of the throat and upper respiratory tract, causing asphyxiation. Rapid buildup of fluid in the lungs may be fatal. It can also interfere with the oxygen-carrying capacity of the blood, causing headache, fatigue, mental confusion, dizziness, and blue color in the skin, especially around the lips. It can even produce serious burns of the skin and eyes (including blindness) and at high concentrations can damage the teeth. Long-term chronic exposure can cause serious respiratory problems including asthma and permanent damage to the lungs, heart, and nervous system. NO<sub>x</sub> has also been shown to be capable

of genetic damage including deoxyribonucleic acid (DNA) damage, mutations, and other aberrations, as well as damaging developing fetuses and decreasing fertility in women.

### REGULATIONS ON HUMAN EXPOSURE

The EPA limits the average annual concentration of nitrogen dioxide in ambient air to 0.053 ppm. The Occupational Safety and Health Administration (OSHA) list a maximal permissible exposure limit (PEL) of 25 ppm for nitric oxide averaged over an eight-hour-day, 40-hour workweek and a limit of 5 ppm of nitrogen dioxide over 15 minutes. The National Institute of Occupational Safety and Health (NIOSH) has set an immediately dangerous to life and health (IDLH) limit of 100 ppm for nitric oxide and 20 ppm for nitrogen dioxide.

In order to reduce NOx emissions from coal-fired plants, new clean-burn technologies are required by the Department of Energy. Staged-combustion low-NOx burners have now been installed on 75 percent of plants and reduce NOx emissions by 40–70 percent or to 0.25–0.65 pound of NOx per million British thermal units (BTUs). New Clean Air Act and Clean Air Interstate Rule regulations restrict NOx emissions to 0.15 pound (0.07 kg) per million BTU for the District of Columbia and 22 states: (Massachusetts, Rhode Island, Connecticut, New York, New Jersey, Pennsylvania, Ohio, Michigan, Wisconsin, Illinois, Indiana, Missouri, Kentucky, West Virginia, Maryland, Delaware, Virginia, North Carolina, Tennessee, South Carolina, Georgia, and Alabama). In order to meet these new regulations, several new technologies have been developed including selective catalytic reduction, a new generation of low-NOx burners, water injection technology, advanced reburning of fuel, and oxygen-enhanced combustion, which can reduce emissions by as much as 80–90 percent. As a result of these efforts, NOx pollution over the eastern United States decreased by about 40 percent between 1999 and 2006. Unfortunately, there are “grandfathered” old coal-burning plants that were not required to meet the stringent guidelines. They emit 10 times as much NOx pollution as the modern plants. Between 1992 and 1998, the amount of electricity produced by these old plants increased by 15.8 percent before the new standards reduced their usage.

The 1997 Kyoto Protocol, which was ratified by 54 countries excluding the United States, which refused, requires a substantial reduction in greenhouse gases including nitrous oxide. Many of the goals of this agreement were required to be satisfied by 2010. This is the second world agreement to

reduce NOx. The first was the 1988 Sofia Protocol to control emissions of NOx or their transboundary fluxes. Most of the 25 participating countries agreed to reduce NOx emissions to 1987 levels and freeze them. In this agreement, the United States volunteered to reduce NOx emissions to 1978 levels.

**NOx emission control systems** Nitrogen oxides, or NOx, are formed by three mechanisms. In a combustion chamber such as a furnace or incinerator, molecular nitrogen (N<sub>2</sub>) present in the atmosphere can become thermally bonded to the oxygen in the air being fed into the system for combustion. NOx produced in this way is called thermal NOx, and its formation is dependent upon flame temperature and fuel availability. The higher the temperature and the leaner the air-to-fuel ratio, the more oxygen will be available for reaction with molecular nitrogen in the hot region of the flame. More NOx, therefore, will be produced.

The second way NOx is produced occurs when fossil fuels, including coal, oil, and natural gas, release the nitrogen they contain in their molecules into the atmosphere during combustion. This NOx is called fuel NOx and is associated primarily with coal and heavy oils. As with thermal NOx, the for-

mation of fuel NOx is dependent upon flame temperature and the ratio of combustion air to fuel.

The third way NOx is produced during combustion occurs when nitrogen combines with hydrocarbons in the fuel to create hydrogen cyanide (HCN). The HCN is oxidized to NOx within several microseconds. This NOx is called prompt NOx and is made in significant amounts only in fuel-rich combustion mixtures and is produced by high-speed reactions in the hottest part of the flame. Generally, prompt NOx is a minor part of total NOx production, especially when natural gas is being burned.

### CONTROL OF NOx

The technologies available to control the release of NOx can be divided into two broad categories, source controls and postcombustion controls. Source controls are those that reduce the amount of NOx created in the combustion zones of the furnace as the fuel is being burned. These include low-NOx burners (LNBs) and combustion controls. Postcombustion controls are those that reduce NOx concentrations in the exhaust gas as it exits the stack, vent, or tailpipe. Postcombustion control technologies include selective and nonselective catalytic reduction, conventional reburning, and fuel-lean gas reburn (FLGR).

For the burning of a relatively clean fuel, such as natural gas, which has a low nitrogen and sulfur content, not much NOx is generated. For fuels with higher nitrogen and sulfur content, such as coal and oil, production of NOx can be significant. One way to lower NOx concentrations during fuel burning is to lower flame temperature. This is done by modifying the burner to increase its surface area, creating a larger but lower-temperature fire. These types of low-flame combustion systems are called low-NOx burners, or LNBs.

Combustion control is another method that can be used to reduce NOx concentrations in exhaust gases. This technology involves the use of a series of techniques to manage the combustion process and increase the efficiency of the burner. Staged combustion allows the initial firing to take place in a high-temperature, fuel-rich zone, where more fuel is present than air available to burn it. Combustion is then completed in a lower-temperature, fuel-lean zone, where there is more air than fuel present. If oxygen is not present in sufficient amounts to combust all of the fuel in the fuel-rich, oxygen-deficient zone, formation of NOx is very limited. Combustion in the secondary zone is conducted at lower temperature, reducing the amount of NOx produced. Low-NOx burners also can be used in combination with staged-combustion technology.

In secondary air staging, also called overfire air, a portion of the air for combustion is redirected to above the level where fuel is being added. Doing this allows the unburned materials leaving the main combustion zone to ignite when mixed with this added, overfire air. In a similar process, using flue gas recirculation, the hot gases created by combustion (flue gas) are directed back into the combustion zone, to lower flame temperature and oxygen content, thereby reducing NOx formation.

If one or several of these approaches are combined into a single unit, it is called a NOx burner. These types of systems can reduce NOx generation by as much as 30–50 percent, although they also reduce boiler efficiency, resulting in higher operating costs.

### Example of the University of California

The San Diego Air Pollution Control District (SDAPCD) has some of the toughest emission standards in the United States, and the University of California at San Diego (UCSD) has to comply with these standards just as any business or company does. As part of its physical plant, UCSD operates three 40-year-old boilers that provide steam for heating and other building operations. The emissions from these boilers were having trouble consistently meeting the SDAPCD's 30-parts per million (ppm) NOx discharge limit. Rather than replace or upgrade the boilers, UCSD hired a specialty-engineering firm that converted them to low-NOx operation. The existing burners, initially supplied with the boilers in 1965, were modified with a computerized combustion control system. Although some equipment had to be upgraded, including installing a variable speed drive to manage the combustion air fan better, the new combustion control system resulted in a reading of 16 ppm, the lowest recorded NOx in the SDAPCD. The length of time required to recover the installation cost through reduced operating expenses for the system was a very fast nine months.

### POSTCOMBUSTION NOx REDUCTIONS

It is not always possible to reduce NOx concentrations in stack emissions to the mandated regulatory level only through combustion control and low-NOx burner technologies. To meet levels mandated by the Clean Air Act and other regulations, a postcombustion processing technique has to be applied on the "downstream" side of the burner. Dependent on the emission limits that need to be met, either a selective catalytic reduction (SCR) or selective noncatalytic reduction (SNCR) technology can be used.

Selective catalytic reduction (SCR) chemically treats combustion gases to convert NOx to inert

nitrogen gas or  $N_2$  and water. Before being discharged from a vent or stack, the exhaust gas is passed through a reactor or catalyst bed, usually made with vanadium, titanium, or platinum, where it is mixed with ammonia and air or steam. On the surface of the catalyst, the ammonia reacts with the NOx to form molecular nitrogen ( $N_2$ ) and water as follows:

Typical NOx reduction efficiencies of SCR systems are 75–90 percent. SCR systems, however, are expensive to install and difficult to operate and maintain. The catalytic reaction works best at temperatures of 400–800°F (204–427°C). If the temperature is too low, excess ammonia fumes are discharged. If it is too high, additional NOx is produced. Also, the reactor bed is easily poisoned or contaminated by dust, sulfur, or chlorine compounds, which need to be filtered or treated before exhaust gases are allowed to contact the catalyst.

Catalytic reduction also is used to help lessen NOx concentrations from automobile exhaust. In an automotive catalytic converter, the reduction catalyst is platinum and rhodium. As gasoline is burned, the resulting NOx vapors have contact with the catalyst, which separates the nitrogen molecules from the oxygen molecules. These nitrogen molecules eventually combine to form inert atmospheric-type nitrogen ( $N_2$ ), while the oxygen is released in the form of  $O_2$ .

Selective noncatalytic reduction (SNCR) is a post-combustion process that also involves the injection of a NOx reducing agent, such as ammonia or urea, into the exhaust gas stream. A reducing agent is an element or compound that is used to remove oxygen from another compound. In contrast, oxidizing agents combine or add oxygen to other elements or compounds. The only problem is that SNCR requires high temperatures, 1,400–1,600°F (760–871°C). Under these conditions, the ammonia or urea separates the NOx in the exhaust gases into water and atmospheric nitrogen. SNCR can reduce NOx by 20–60 percent.

Conventional reburning can result in significant levels of NOx removal without the use of chemical reagents or catalysts and, in some cases, without modifying or replacing existing burner equipment. In conventional reburning, natural gas is injected above the primary combustion zone to create a fuel-rich and air-lean zone, where NOx is reduced. Additional overfire air is then introduced above the reburning zone to complete combustion. The objective of conventional reburning is to create a reducing environment within the combustion chamber that

converts NOx formed in the primary combustion zone to molecular nitrogen. Conventional reburning can reduce NOx emissions by 50–70 percent. An added benefit of introducing natural gas into the combustion process is that by substituting or replacing part of the burner's standard fuel with natural gas, less SOx,  $CO_2$ , and particulate (particulate matter with a diameter of 10 microns or less [PM-10]) is created. Conventional reburning can be used as a stand-alone approach to NOx control or in conjunction with other source control or postcombustion processes, such as low-NOx burners.

### FUEL-LEAN GAS REBURN (FLGR)

Fuel-lean gas reburn (FLGR) is a patented NOx control technology in which natural gas is fed into the upper regions of the burner to establish a local air-rich and fuel-lean combustion environment. The natural methane gas forms hydrocarbon radicals that react with the NOx produced during combustion to form HCN, or hydrogen cyanide. This HCN then undergoes a further series of reburning reactions within the locally fuel-rich upper region of the burner, eventually transforming the NOx into elemental nitrogen, or  $N_2$ . Maintaining the correct balance between the injected natural gas and the burner's standard operating fuel of coal, natural gas, or oil is critical to effective NOx removal. If it is done correctly, NOx reductions of 35–45 percent can be achieved.

### Example of Riverbend Unit 7

Riverbend Unit 7, operated by Duke Power, is a 140-megawatt tangentially fired coal-burning utility boiler, which began operations in 1954. Located near Mount Holly, North Carolina, Riverbend Unit 7 is named for a bend in the Catawba River. Duke Power operates almost 30 tangentially fired boilers where pulverized coal and combustion air are introduced through the corners of the boiler in such a way that the mixture intersects the outside of an imaginary circle in the middle of the furnace. Duke Power, one of the more environmentally proactive utilities in the United States, previously installed low-NOx burners on Riverbend Unit 7 to meet acid rain requirements of the 1990 Clean Air Act Amendments. With these modified burners, Riverbend Unit 7 produced 0.40–0.45 pound (0.18–0.2 kg) of NOx emissions per million British thermal units (BTUs) of heat produced. Duke Power recognized that an additional approximately 45 percent reduction in NOx emissions would soon be required by even stricter air quality regulations. They investigated the use of FLGR to determine whether it was a more cost-effective option than either conventional reburning or SNCR.

FLGR proved to be a very cost-effective emission control technology because of the easy access to nearby natural gas supplies. The FLGR system installed and operated at Riverbend Unit 7 resulted in significant NOx reductions, although elevated CO emissions became an issue during early system operations. Once modifications were made to the gas injection system, CO emissions decreased dramatically, and the performance of FLGR improved. If FLGR can be used successfully on all the tangentially fired boilers in Duke Power's generating system, it will allow this utility to attain a 40 percent reduction in NOx emissions and could potentially reduce the utility's capital cost of compliance with air pollution control requirements by approximately \$70 million.

FLGR is an attractive technology, not only for Duke Power but also for many other utilities, because it can be a relatively inexpensive addition to existing combustion systems, without the need for a major overhaul or retrofit. It also is a compatible add-on or supplemental technology with other NOx control systems.

**ocean dumping** People have utilized the oceans for food, transportation, and recreation for millions of years. Unfortunately, up until very recently, humans have also used the ocean as a dumping ground. Unlike marine litter or ships' sewage, which are accidentally, randomly, or even, at times, secretively released, ocean dumping is the direct release or discarding of waste materials, usually from a barge or ship, at a specified place on the ocean floor. Over the last century, the United States and other countries have intentionally disposed of a vast amount of unwanted materials at sea. An estimated 25 million tons (22.7 million metric tons) of industrial waste was dumped into the ocean during the 1970s and 1980s alone.

These vast, seemingly limitless expanses of ocean floor, remote from population centers, appeared to be the perfect place to dispose of sewage sludge, scrap metals, mine tailings, radioactive waste, pesticides, and other types of organic compounds. Encouraging this “out-of sight, out of mind” approach to ocean dumping was the lack of scientific information on ecosystems that might be present at the bottom of the sea.

This attitude began to change as deep sea submersibles and other deep ocean exploration techniques began to be developed in the early 1970s. One groundbreaking study, done in 1982 by Woods Hole Oceanographic Institute, identified almost 800 different species of sea life at depths of more than 6,000 feet (1.8 km) off the east coast of New Jersey and Delaware. This high degree of biodiversity increased to the south as water temperatures warmed, and it is thought that there may be more than 10 million different species present on each half-square-mile (1.3 km<sup>2</sup>) of ocean floor, even at

depths greater than 3,000 feet (0.9 km). This study and other research have demonstrated that near-shore ocean floor habitats may be just as ecologically alive and vital as equivalent land-based systems. Just as in sensitive terrestrial habitats, ocean dumping can disrupt these ecosystems and result in significant harm to marine life, ultimately damaging fisheries and other food sources.

### MAJOR POLLUTANTS

Trash, industrial waste, and sewage sludge often contain pesticides or heavy metals such as lead, copper, and cadmium that can be concentrated in sediments and eventually work their way into the food chain. Through bioaccumulation, fish and sea mammals could be poisoned, reducing their ability to reproduce or making them unsuitable for human consumption. Dumping of certain organic wastes lowers the dissolved oxygen level in the water and thereby can kill off clam beds and other shellfish that many commercial fish and people rely on for food. This occurs through *eutrophication*, a biological process in which nitrogen and phosphorus present in waste allow oxygen-depleting bacteria to proliferate. In turn, these organisms create a hypoxic, or oxygen-poor, environment that kills other essential marine life.

Pathogens including bacteria, viruses, and other disease-causing organisms that are disposed of at sea with the waste material have caused fish to be infected with such illnesses as black gill, or bacterial gill disease. This condition is characterized by the growth of filamentous bacteria on the gills and leads to a fusing of the gill filaments. The infection reduces the gill's respiratory efficiency, eventually killing the fish.

## AIR POLLUTION OVER THE OCEAN

There are few experiences as refreshing as standing on the beach in the evening and enjoying the feel of an onshore ocean breeze. Unfortunately, the quality of the air in that breeze is under attack from a variety of both land- and ocean-based air pollution sources. The manufacturing and related commercial activities that support the economies of developed and developing countries place enormous pressures on the natural cleansing and pollution attenuation mechanisms that operate within the oceans. More important, pollution associated with inland industrialization, including its by-products of desertification and soil erosion, is often directly translated to environmental degradation of marine air quality.

### LAND-BASED POLLUTION SOURCES

The release, long-distance transportation, and settling, or deposition, of atmospheric pollutants from both natural and industrial land-based sources have been widely recognized as significant contributors to oceanic and surface water body pollution. This can occur either directly, as winds carry pollutants from their sources far out into the ocean, or indirectly, as rivers and streams flush pollutants into harbors and estuaries. Three processes operate to deposit air pollutants to surface water: gas exchange, dry deposition, and precipitation.

#### 1. Gas Exchange

Semivolatile organic compounds such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), mercury, and certain types of pesticides have the unusual property of being able to exist in the atmosphere in both a particulate (solid) phase and a gas phase. Their low vapor pressure and relatively insoluble nature make them able to evaporate upon release into the environment (e.g., pesticide sprayed onto a field). Once in the atmosphere, semivolatile compounds can travel long distances by cycling between the gaseous and solid states. They are deposited, volatilized, and remobilized as atmospheric conditions change according to season. Once in the ocean or other surface water body, their resistance to natural degradation by bacteria, sunlight, or other biochemical processes allows them to accumulate in the water column or sediments, where they eventually enter the food web, taken up by plants, phytoplankton, or other primary producers.

#### 2. Dry Deposition

This process takes place as particulate matter settles out of the atmosphere directly into the ocean or surface water body. It is a continuous process and under natu-

ral conditions is beneficial, providing a steady stream of mineral-rich dust to microscopic marine plant and animal life far from the shore. If toxic contaminants such as hydrocarbons, lead, or dioxins are attached to the particulate, however, measurable impacts to environmental quality and aquatic life can occur. Pesticides such as dichlorodiphenyltrichloroethane (DDT), chlordane, and toxaphene have been detected at high levels in the blubber of Arctic whales, where such substances have never been applied. More than 1,000 miles (1,609 km) from shore over the Indian Ocean, scientists have measured a 1¼-mile- (2-km-) thick layer of haze that reduces visibility to less than six miles (10 km), similar to many polluted areas on land. This haze consists primarily of soot, sulfates, nitrates, organic particles, fly ash, and mineral dust and presumably emanates from Asia and the Indian subcontinent. The presence of such a dense, widespread layer of pollution so far from land-based sources raises concerns over the effects of reduced sunlight on aquatic organisms and increased rates of radiational cooling from higher rates of reflected sunlight.

#### 3. Wet Deposition/Precipitation

Both gaseous and particulate pollutants can be incorporated into cloud droplets and be flushed into the ocean or surface water by rain, snow, or ice pellets (sleet). They can also be removed from the atmosphere as nonpolluted precipitation falls through and absorbs the contamination. The capture of pollutants by wet deposition is highly dependent upon the solubilities of the materials. More soluble compounds such as SO<sub>x</sub>, nitrobenzene, and acetonitrile are more susceptible than relatively insoluble compounds such as pesticides and PCBs. Airborne dispersion and wet deposition processes ensure that pollutants are not necessarily deposited in the same country where they were released. In 1998, for example, 25 percent of the sulfur oxides deposited on the United Kingdom were from other countries. That same year, 90 percent of the sulfur oxide pollution washed out of the atmosphere in Sweden and Norway blew in from across the Baltic Sea and the Gulf of Bothnia.

### OCEAN ACIDIFICATION

As the amount of carbon dioxide (CO<sub>2</sub>) in the atmosphere rises as a result of the increased burning of coal and other fossil fuels, some of it is taken up by the

*(continues)*

(continued)

terrestrial biosphere (i.e., plants), and the rest settles into the oceans either dissolved in rainwater or as carbonic acid ( $\text{H}_2\text{CO}_3^-$ ), bicarbonate ( $\text{HCO}_3^-$ ), or carbonate ( $\text{CO}_3^{2-}$ ), depending upon temperature, ocean salinity, and several other factors. Ocean absorption of  $\text{CO}_2$  is a critical component of the carbon cycle as it helps to moderate the amount of  $\text{CO}_2$  in the atmosphere and thus the Earth's climate. Excessive amounts of  $\text{CO}_2$  released since the beginning of the Industrial Revolution, however, have started to overwhelm the natural system of atmospheric carbon checks and balances and may be leading to fundamental changes in ocean chemistry. Acidification also has been related to increased amounts of sulfur dioxides, produced by the burning of fossil fuels. Sulfur dioxides combine with rainwater and surface water to form sulfuric acid.

As the oceans absorb more  $\text{CO}_2$ , hydrogen ion ( $\text{H}^+$ ) concentration increases, lowering ocean water pH and raising the level of acidity. Recent studies predict that by 2100, ocean water pH will decrease by up to 1.4 standard units as it struggles to take in the overabundance of carbon dioxide present in the atmosphere. This absorption, termed ocean acidification, will aid in reducing the amount of carbon in the atmosphere. On the other hand, it puts a wide variety of aquatic organisms at risk. Calcium deficiencies have already been documented in fish and other types of marine life. They result in weakened bones and brittle eggs, as well as damaging the ability of gills to absorb oxygen from seawater. Toxic metals present in ocean sediment (aluminum, arsenic, cadmium, and mercury) become more mobile and bioavailable under acidic conditions. Similar effects have been observed in freshwater bodies such as lakes and estuaries.

More importantly, acidification threatens the very foundation of the ocean's food web, namely, corals, coccolithophores, some types of pteropods and foraminifera, as well as many other types of free-floating and benthic life-forms. These organisms have exoskeletons made of calcium carbonate ( $\text{CaCO}_3$ ), which becomes very unstable and more soluble as seawater becomes more acidic. The calcareous phytoplankton and zooplankton most affected by ocean acidification form the base of the marine food web and make up 95 percent of the primary producers in the ocean. Ocean phytoplankton make up approximately 1 percent of the Earth's biomass but are responsible for about half of the photosynthetic activity on the planet. These organisms remove  $\text{CO}_2$  from the atmosphere and release valuable oxygen. Without a healthy and thriving pelagic population, the oceanic food web will col-

lapse and with it so will a major source of sustenance and commerce for the world. The potential for ocean acidification to result in a catastrophic failure of the Earth's oxygen nutrition engines provides a real impetus to expand efforts to improve control and reduce emission of greenhouse gases.

### MARINE ENGINE EXHAUST

Diesel fuel is especially well suited for use in marine vessels. It has low volatility and high flash point ( $150^\circ\text{F}$  [ $65.6^\circ\text{C}$ ] versus  $30^\circ\text{F}$  [ $-1.11^\circ\text{C}$ ] for gasoline), which make it safer to use in the tight confines of a ship's engine room. Diesel engines are more efficient than gasoline engines, burning 20–30 percent less fuel to generate the same amount of horsepower and, as such, are cheaper to operate. Also, given diesel's low autoignition temperature ( $446^\circ\text{F}$  [ $230^\circ\text{C}$ ] compared to  $1,022^\circ\text{F}$  [ $550^\circ\text{C}$ ] for gasoline), the amount of waste heat this type of engine generates is low. As an added benefit, diesel engines can be scaled up to very large sizes and provide the enormous amounts of torque needed to push a ship through the water.

In terms of their exhaust, engines burning diesel fuel produce much less carbon monoxide (CO) than gasoline engines; that is why truckers can leave their engines running overnight while they sleep. Diesel engine exhaust, however, contains large amounts of nitrogen oxides, particulate, and hydrocarbons in the form of soot or unburned carbon particles. The characteristic black smoke given off by diesel engines is caused by insufficiently atomized fuel because injectors are faulty or because more fuel is being injected than can be burned in the motor's combustion cycle, otherwise known as the black smoke limit.

The environmental and public health effects of diesel exhaust can be significant. Particulate matter given off with this type of exhaust contains a high coarse fraction (particulate matter with a diameter of 10 microns or less [ $\text{PM}_{10}$ ]), which has been linked to such respiratory diseases as asthma, emphysema, and possibly cancer. Nitrogen oxides and sulfur oxides, which are also present in diesel emissions, contribute to ocean acidification and may disrupt nutrient cycles by causing local increases in nitrogen concentrations leading to eutrophication. Particulate can also temporarily reduce local visibility and incoming sunlight, thus impacting photosynthetic marine organisms.

On a global basis, marine diesel exhaust makes up about 7 percent of emitted  $\text{NO}_x$  and 4 percent of  $\text{SO}_x$ . In the United States, annual diesel exhaust emissions from container and cruise ships at the 10 busiest ports produce the same amounts of  $\text{NO}_x$  and  $\text{SO}_x$  as more

than 3 million and 18 million cars, respectively. Considering that the amount of maritime shipping is expected to double by 2020, diesel exhaust will contribute significantly to the growing pollutant load in the Earth's atmosphere.

### REGULATIONS ON OCEAN AIR POLLUTION

Fortunately, the global community is taking steps to address this problem of diesel exhaust. In 1997, the UN's International Maritime Organization (IMO) passed Annex VI to the International Convention for the Prevention of Pollution (MARPOL 73/78) from oceangoing vessels. The IMO is an international agency responsible for developing standards for the use of the world's oceans. This includes not only environmental, but also ship operation/safety standards, resource exploitation including fishing and oil exploration, and other ocean-related activities. Once a standard is promulgated, it becomes international law after its ratification by a certain number of member countries. Annex VI, which took full effect in 2005, establishes limits on the sulfur and nitrogen oxide emissions from ship exhaust and totally prohibits the release of ozone-depleting substances. Exceptions are made for emergencies when the integrity of the ship or safety of the crew is at risk. These exceptions mainly apply to the operation of diesel-fired emergency pumps. Annex VI also established the North Sea and Baltic Sea as Special SO<sub>x</sub> Emission Control Areas (SECAS), where only very low-sulfur diesel fuel (1.5 percent or less) can be used.

The maritime shipping industry has taken a multi-phase approach to meet the requirements of Annex VI. As low-sulfur fuel is expensive and often difficult to obtain, many shipowners have started to install emission scrubbing systems on their vessels. Some

have started to "slow steam," which burns less diesel fuel so that emission standards can be met, although market pressures associated with delivery schedules do not make this an attractive option. Other shipping companies have divided their fuel tanks into low-sulfur diesel and regular sulfur diesel systems. Low sulfur is burned in SECAS designated zones and regular sulfur diesel is used outside those zones. Still others have decided to use low-sulfur fuels for all maritime operations (the green option). Regardless of the approach being used, the days of unfettered air pollution from seagoing vessels are rapidly coming to an end.

### LEGISLATION ON MARINE DUMPING

In the United States, restrictions on ocean dumping were instituted in 1972, when Congress passed the Marine Protection, Research, and Sanctuaries Act. For the first time, a permit was required to dispose of materials in the ocean. General permits were issued for activities found to have a minimal environmental impact, such as burials at sea, the sinking of U.S. Navy target vessels, and the disposal of vessels in the ocean. More importantly, special permits were required by any person wishing to discard material into the ocean or to transport material from the United States for ocean dumping. Material that was used for biological warfare or had high levels of radioactivity could no longer be disposed of at sea.

In the late 1980s, legislators were galvanized into further action when syringes, vials of blood, and other medical waste washed up on beaches in New York, Connecticut, and New Jersey after heavy spring rains. The 1988 Ocean Dumping Ban Act and Public Vessel Medical Waste Anti-Dumping Act were passed and signed into law. These acts added sewage sludge, industrial waste, and medical waste to the list of materials that could no longer be discarded into the ocean. Exceptions are allowed to protect the health and safety of the crew or in the event of war or national emergency. These and other regulations have been effective in reducing the amount of ocean dumping. As a result, dumping of sewage sludge was reduced from 18 million tons (16.3 million metric

tons) in 1980 to a little more than 12 million tons (10.9 million metric tons) for all of the 1990s.

Internationally, the pressure to curtail ocean dumping started to build in the early 1970s. The United Nations General Assembly convened the 1968 Conference on the Human Environment and another in 1972 to focus on issues that laid the groundwork for today's environmental consciousness. Effectively describing the threat to the ocean that indiscriminant dumping posed, these beginnings led to the Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter, a 1975 meeting in London that established guidelines on the ocean disposal of industrial wastes. In November 1993, signatory countries to the London Dumping Convention, as it came to be known, also agreed to ban the disposal from ships of radioactive waste. More than 80 countries signed these prohibitions, which were similar to those put into place by the United States. The United Nations International Maritime Organization was given responsibility for this agreement and a more formal protocol was adopted in 1996. Many poorer countries, however, continue to struggle with both enforcement of ocean dumping bans and the development of alternate disposal methods.

Waste materials discarded into the seas are called black list, gray list, or white list items. Black list wastes are chemicals such as organohalogens, mercury, cadmium, plastic, petroleum products, highly radioactive substances, and biological or chemical warfare agents. Gray list materials include arsenic, copper, lead, zinc, organosilicon-contaminated liquids, cyanide, fluoride, pesticides, acids and bases; certain metals, such as beryllium, chromium, nickel, nickel compounds, and vanadium; and scrap metal, low-level radioactive materials, and other compounds that affect the ecosystem. White list items are all other materials not included on the black or gray lists. These are materials that can be safely discarded, so long as it is not done in vulnerable areas, such as coral reefs.

### DREDGING AND SPOILS

Today, the majority of environmental concerns related to ocean dumping are focused primarily on the unrestricted, open-water disposal of dredge spoils. To keep ports and harbors accessible to boat traffic for recreation, commerce, and defense, several hundred million tons of silt and sediment that accumulate naturally in coastal channels and near docks and other harbor facilities must be periodically removed. Dredging is done to remove sediments that have been contaminated by industrial pollutants. In the United States, almost a half-billion

cubic yards (394 million m<sup>3</sup>) of sediment is dredged annually by federal, state, and local governments, as well as by private organizations such as cargo terminals, marinas, and yacht clubs.

The dredged material is removed from active shipping channels, ports, and harbors; some of it (about 10 percent, according to U.S. Environmental Protection Agency [EPA] estimates) is typically contaminated with heavy metals and organic chemicals such as hydrocarbons or pesticides that were released into the water from ships and harbor operations, as well as carried downstream by runoff from farms, roads, and discharges from industrial sites and wastewater treatment plants. Until the early 1990s, most of this dredged material was loaded onto ships or barges and dumped farther offshore at specially designated sites, away from seagoing traffic. There were concerns, however, about the ecological impacts of concentrating potentially contaminating sediment in one place and its possible relocation by ocean currents. In response, other disposal alternatives are now used to manage about 80 percent of dredged material nationwide.

These disposal alternatives include either confined disposal or beneficial reuse. Confined disposal is the placement of contaminated dredged material within an excavated offshore area or in a secure upland area where its potential effect on the environment can be minimized. In New Jersey, the 70-foot- (21.3-m-) deep Newark Bay Confined Disposal Facility is intended to isolate contaminated sediment dredged from shipping lanes in the harbor cost-effectively. Beneficial reuse entails collection and relocation of noncontaminated dredged material for reuse as either landfill cover, road base, mine reclamation, or other types of "upland fill" in construction, land restoration, or habitat creation projects such as beach replenishment and island creation.

Decontamination technologies also are being developed to treat contaminated dredge materials and allow them to be more widely reused. Although treatment costs are a factor, especially because some projects require the management of thousands of tons of material, as the costs of decontamination and placement decline, this approach is becoming a more viable option.

To excavate dredge material within the navigable waters of the United States, a permit must be obtained from the U.S. Army Corps of Engineers (USACE). Permit applications are evaluated against environmental criteria developed by the EPA to protect the marine environment and assess potential impacts of ocean dumping on human health, shipping and transportation needs, and marine resources such as fisheries and recreation. If approved, dredging and disposal

activities are monitored by the USACOE and EPA to ensure that permit conditions including excavation depths, amount of material removed, handling, and disposal are followed. Similar permits are required for dredging projects in most industrialized countries, and the United Nations is helping developing nations to establish their own dredging control programs.

### COMMONLY USED DREDGING TECHNIQUES

Name	Description	Application
Clearing and snagging	Special boats equipped with cranes winches, and grappling hooks are used to clear debris, unused piers, and sunken objects from channels and shipping lanes.	Used to remove large items or break up debris that has become a hazard to navigation.
Grab dredge	One or more crane-operated buckets mounted on a barge or a fixed shore facility. Each bucket has a hinged jaw, which closes when sunk into the sediment. Material is lifted to the surface and placed in a hopper for transport to a disposal area.	Used when relatively low volumes of material are excavated.
Dipper dredge or boom and dipper assembly	Similar to a power shovel, mounted on a movable or fixed platform, a cable operated scope is used to dig out sediment or soil for placement in trucks or hoppers.	Used in areas where access to construction equipment is not readily available. Very rugged and capable of removing hard-packed material. Also used in land-based canal digging and cutting projects. This technique was used to excavate the Panama Canal.
Ladder bucket or hopper dredge	Usually mounted on a ship built with a long, narrow opening (called a well) in the hull. A string of buckets, mounted on a steel frame above the well, is lowered into the water and used to scoop up sediment. Each bucket empties its load into a chute connected to either a barge or a bottom-emptying hopper.	Used when large volumes of material must be removed quickly and inexpensively from active shipping lanes. Works best in deep waters but cannot dredge continuously, and excavation is less precise than with other techniques.
Suction or hydraulic dredge (cutterhead dredge and self-propelled hopper dredge)	Material is sucked through a flexible hose mounted on the intake end, with a water jetting device that mixes and breaks up bottom sediment. At the discharge end, sediment is emptied into a hopper, where it settles and excess water is decanted.	Used primarily for the almost-continuous removal of soft sand or sediment but can excavate smaller loose rocks and debris. Material dredged in this manner can be moved through pipelines for long distances and be used in land reclamation activities. May be difficult to operate in rough weather.
Dustpan and sidecaster dredge	Dustpan dredge is a type of hydraulic dredge designed specially for the Mississippi River. Water jets at the end of the suction head agitate the sand into a slurry, which is then pumped up into the dredge. The discharge is sent to a pipeline and emptied a short distance, typically around 800 feet (246 m), outside the navigable channel. A cutterhead dredge has an active rotating auger surrounding the suction line. The material can be pumped much farther through a pipeline, up to 3,000 feet (0.9 km).	Used to remove loosely compacted, coarse-grained material in shallow sites or in areas where sediment can be used adjacent to or near the channel.

Note: Hopper barges are designed with hinged doors, or flaps that open downward. Around the storage space (cargo hold) are watertight compartments that provide buoyancy for the barge. When the barge is above the disposal site, the bottom doors open and sediment is released. Winches then close the doors and the barge is ready to receive its next load.

**offshore oil production** In 2000, offshore oil production was more than 25 million barrels (3,975 million L) per day and accounted for more than 30 percent of global petroleum supplies. Similarly, offshore wells provided some 30 trillion cubic feet (0.9 trillion m<sup>3</sup>) of natural gas in 2000, with another 6 trillion cubic feet (0.2 trillion m<sup>3</sup>) of production expected by 2020. There are large reserves of petroleum and natural gas on the outer continental shelf of the United States, especially off the coasts of California and Alaska and in the Gulf of Mexico. One study estimated that 30 percent of the undiscovered gas and oil reserves in the United States is within its coastal territorial waters.

### DEEP-SEA DRILLING

The exploitation of these reserves has a steep environmental price tag. The process begins with finding the oil or natural gas, which typically is done through prospect mapping using geophysical surveys and results from other wells. The objective is to find a geological structure, called a trap, where oil or gas has accumulated and can be extracted. Once the subsurface structure or trap has been identified, a series of exploratory wells are drilled to determine whether oil or gas is present in economic quantities. If so, a series of development wells are drilled to remove the petroleum. Three basic types of equipment are used to drill a typical offshore oil well. These include a drillship, with drilling equipment mounted on its deck that can be advanced through an opening in its hull. Anchors often are driven into the sea bottom to allow the drillship to maintain its position. More sophisticated systems, however, use a series of powerful computer-controlled thruster engines mounted on the ship to stay on station over the borehole. Drillships can operate in waters 2,000 feet (610 m) deep or more.

A jackup rig is a floating barge equipped with massive extendable legs that is towed to the well site. The legs are lowered onto the seafloor and raise or "jack up" the barge off the surface of the water so that it becomes a more stable drilling platform. These types of rigs can be used only in relatively shallow water (less than 500 feet, or 152 m, deep).

A semisubmersible is also mounted on a barge, but instead of extendable legs, the barge is equipped with large pontoons. Once on station, the pontoons are flooded and drag the hull of the barge down to just below the waterline. It is then anchored to the seafloor with cables. This type of setup can be used in waters between 500 feet (152 m) and 2,000 feet (610 m) deep.

Once the location for an offshore oil or natural gas well has been identified, a more permanent drilling platform is constructed. Usually installed on fixed legs, platforms are very large steel-shelled structures with a deck extending just above the water line. The deck rests on a complicated series of large-diameter pipes (the "jacket") welded together and extending to the seafloor. Once the well is drilled to the desired depth, the oil or gas is delivered into a subsea pipeline. Many of these pipelines are hundreds of miles long and connect platforms to a refinery or distribution center.

Each of these steps, exploratory drilling, and platform installation, followed by laying of pipeline, can negatively affect the marine environment. Environmental effects of well-conducted exploratory oil drilling are usually short-term and modest. Care must be exercised to avoid fish-spawning or other ecologically sensitive areas and to ensure that waste products from equipment operation are managed appropriately. In the construction of the more permanent structures, however, habitat for benthic organisms, many of which form a critical part in oceanic food webs, can be destroyed. Fish and other marine organism breeding or migratory patterns also can be disrupted. Pipelines can leak and discharge oil into the ocean, and waste from drilling and platform maintenance can result in localized pollution. Unquestionably, however, the chief environmental risk posed by offshore oil and gas production is a blowout.

### BLOWOUTS

The oil and gas present in the geologic reservoir, or trap, are under immense pressure because they are buried beneath thousands of feet of sediments below the ocean floor. Unless special precautions are taken during drilling, when the well penetrates the accumulation, oil and gas rush to the surface in

an uncontrolled release, called a blowout. Blowouts often result in intense fires because of the flammable nature of the oil and gas. The fires are extremely dangerous and very difficult to extinguish. Blowouts

from offshore wells often result in severe ecological damage because the oil is released directly into the ocean, in immediate contact with sea life and their fragile habitats.

**Simplified illustration of a modern petroleum-drilling rig. Basically, the crown block, derrick, and traveling block are involved in installing or removing components from the well. The rotary table provides the turning power to the drill pipe string and ultimately the bit at the base of the well. The drilling mud is pumped by the mud pump through the mud hose and into the well for lubrication and for removal of debris. The casing and blowout preventer keep the mud and petroleum in the well.**

There are two ways to prevent oil well blowouts: mud management and blowout preventers. As the drill bit is advanced into the rock and sediment, the materials crushed by the bit must be removed. This is done by using a mixture of clay and water called drilling fluid or mud. To be effective, the mud must be dense enough to carry the cuttings of rock to the surface, but not so dense as to interfere with the turning of the drill bit. Well drillers train for years in order to master this balancing act. Drilling mud also has another very important purpose. It can be used to keep the oil and gas out of the well until drilling is finished and the well is connected to oil or natural gas collection and distribution pipelines.

During drilling, mud pressures are monitored continuously to ensure that the drilling fluid is heavy enough to keep the oil or natural gas out of the well. The pressure within the well, however, can increase suddenly as unexpected changes in rock types are encountered. This rapid and often unpredictable pressure change, called a kick, can force mud and oil or natural gas up through the well pipe and onto the surface, resulting in a blowout. Carefully checking mud densities and levels, maintaining adequate circulation, and measuring bottom hole pressures, all help to prevent a blowout when a kick occurs.

The use of drilling mud can have significant environmental consequences. These muds are formulated by mixing together natural clays with special additives. Once circulated out of the borehole and on the platform, the mud is processed to remove the rock cuttings and then returned to the borehole. The cuttings, which can contain up to 15 percent of the mud, are discharged into the sea. The following are three basic types of muds used in offshore drilling applications.

#### **Oil-based muds (OBMs)**

These muds are used when drilling through host rock containing minerals, often present in shale, that absorb water. This loss of water results in a loss of borehole pressure that can lead to a blowout. Adding diesel fuel and/or mineral oil to the mud enables it to lubricate more efficiently, allows for better pressure control inside the well, and reduces the chance the drill pipe will become stuck. OBM also is the mud of choice when drilling boreholes that are not vertical. The U.S. Environmental Protection Agency (EPA), however, does not allow the discharge of OBMs or their cuttings from offshore platforms, making their use and management cost-prohibitive except in very limited circumstances. Oil-based muds and synthetic-based muds are

sometimes grouped together in a category called nonaqueous-based fluids, or NABFs.

#### **Water-based muds (WBM)**

Inexpensive and readily available, these types of drilling fluids are made up primarily of clay (bentonite) and either salt water or freshwater and include barite, a barium-rich heavy mineral used to add weight; caustic soda; lignite coal; or lignosulfonates. Water-soluble polymers are sometimes mixed in to stabilize the drilling fluid during use and to reduce corrosion and bacterial activity. WBMs have long been the mud of choice for the drilling companies because the used mud and cuttings can be discharged from platforms in many U.S. offshore waters (except Alaska), as long as they meet permit limits. They typically do not cause significant environmental problems for marine life or benthic ecosystems.

#### **Synthetic-based muds (SBMs)**

The use of synthetic-based muds, in which the base fluid is an organic chemical such as olefins, ethers, esters, or acetal, has been increasing in U.S. waters, as well as offshore operations of other major oil-producing countries. An olefin is an alkene hydrocarbon from ethene. Ether is derived from the distillation of ethyl alcohol with sulfuric acid. An ester is a class of organic compounds produced from an organic acid and an alcohol. Acetal is a class of compounds formed from the oxidation of alcohol. SBMs have several technical advantages over WBMs, particularly when drilling in very deep water or a nonvertical borehole. They generate fewer cuttings than WBMs and are easier to process and recycle. Also, SBMs are not as toxic as OBMs, tend to degrade more rapidly, and are less likely to bioaccumulate. Given these properties, SBM cuttings can be discharged from offshore platforms, although the spent fluids must be contained and sent ashore for treatment and disposal.

The environmental and scientific communities are not in agreement about the way drilling fluids should be managed. Offshore platforms can discharge millions of gallons of mud every day. Once in the ocean, the cuttings and muds can accumulate in significant volumes. Even a small well by today's standards can generate up to 95,000 cubic feet (2,767 m<sup>3</sup>) of cuttings. Several studies have shown that mud and cuttings can inhibit sea grass growth and interfere with coral development. The oil industry has responded by looking at techniques such as mud reinjection and drilling of smaller-diameter boreholes. As regulatory pressure on the management of drilling fluids and cuttings increases, it is only a matter of time until most platforms reach zero-discharge status.

## BLOWOUT PREVENTERS

The second line of defense in blowout prevention is the use of special valves installed on the wellhead. This device, called a blowout preventer, or BOP, forms a seal at the top of the well and is automatically activated to stop the uncontrollable flow, or blowout, of formation fluids (mud, oil, or natural gas). BOPs are fixed atop the wellhead in an array designated as the BOP stack. This array or stack typically contains either a ram, annular, or rotating BOP along with associated valves and piping. These types of BOPs can also be used in combination.

Blowout preventers are mounted directly to the wellhead in combinations, called the BOP stack. This stack may contain one or all three types of BOPs. However, the primary well-drilling control is the hydrostatic pressure exerted by the drilling mud pumped into the borehole. The BOP is the second line of defense and provides a safety margin in the event of a sudden loss of drilling fluid pressure.

## PRODUCED WATER

After an offshore oil or natural gas well goes into production, it generates produced water. Hydrocarbon reservoirs contain water that was deposited along with the organic material that was eventually compressed and distilled over time to make oil. This water is denser than oil and tends to accumulate at the bottom of host rock formation. When oil is pumped from the well, water is drawn up with it. This water must be separated from the hydrocarbon before the oil or natural gas is sent to market. Sometimes, to increase production efficiency, additional water is injected into the reservoir. Both types of

water are called produced water. Its salt content is high, almost 10 percent, and produced water can also contain elevated concentrations of dissolved solids, volatile and extractable organic compounds, ammonia, hydrogen sulfide, and heavy metals, such as arsenic and copper.

Once out of the well and separated from the oil, produced water is managed in several ways. In many cases, it is reinjected into the well. On some platforms, special wells are drilled and produced water is injected into other geologic formations. When there is no other practical alternative, produced water is discharged into the sea. No matter how efficient the treatment process, produced water always contains some amount of oil, and its discharge is carefully regulated. In U.S. waters, the Clean Water Act requires a permit under the National Pollutant Discharge Elimination System (NPDES). These permits regulate the quantity and quality of produced water that can be released from the platform.

Some scientists and many environmentalists maintain that current regulations related to the discharge of produced water are not sufficiently protective. They are concerned that the sheer volume of produced water generated during the operational life of a platform will overwhelm the dilution capability of the receiving body of water. For example, over the next 35 years, more than 2 billion gallons (7.6 billion L) of produced water will be discharged into the Gulf of Mexico. Some studies have detected oil and produced water residues in ocean sediments far downcurrent of platforms, especially those that have been operating for a decade or more.

Several European countries have moved to eliminate the discharge of produced water. Two major

## BLOWOUT PREVENTERS

Type	Description
Ram	Highly reliable and the principal pressure control tool used in oil well drilling. Sealing elements (rams) are on opposite sides of the blowout preventer. Operated by hydraulic cylinders, when open, they provide an unobstructed passage through the borehole. When closed, they seal off the open hole. Some types of rams, when activated in an emergency, will even shear off all the tools at the surface and seal the borehole without the need to remove the drill rods or bit.
Annular	Versatile tool able to seal off the borehole regardless of the tools or drilling equipment present in it. When activated by a piston, annular BOPs form a seal in the open (annular) space between the drill pipe and the borehole. It acts as a tight-fitting collar around the drilling tools present in the well, keeping them in place and preventing a sudden release of pressure.
Rotating	A low-pressure device, used in special situations when the hydrostatic pressure of the drilling fluid is less than the formation pressure, which allows drilling to proceed faster. It is attached to the top of the drill rod by a quick-release bonnet and rotates with it. When activated, the sealing element closes around the drill rod and seals off the borehole.

Norwegian oil fields usually do not discharge produced water, either reinjecting it or storing and offloading it into barges for treatment at land-based facilities.

**Ogallala Aquifer** One of the major aquifers in the United States, the High Plains Aquifer, is predominantly composed of the Ogallala Aquifer, named for the geological formation that contains the aquifer. This aquifer produces 30 percent of all water for irrigation in the United States. It underlies parts of eight states (Colorado, Kansas, Nebraska, New Mexico, Oklahoma, South Dakota, Texas, and Wyoming), covering a total area of 174,000 square miles (450,000 km<sup>2</sup>). This area contains 20 percent of the nation's cropland, making it one of the most important agricultural areas. Use of water withdrawn from the entire High Plains Aquifer is 94 percent for irrigation, with the remaining 6 percent supplying 82 percent of the drinking water needs in the area. Parts of the area contain water that is so saturated with natural contaminants that it is of questionable safety. The major problem, however, is that the huge removal of water from the Ogallala Aquifer is quickly dropping the water levels, creating a serious situation that is currently being addressed by the U.S. Congress.

#### **GEOLOGIC HISTORY**

The Ogallala Formation was named by N. H. Darton in 1898 for the town of Ogallala, Nebraska, where it is best exposed. The major depositional

history of the unit was from Late Miocene–Early Pliocene to Late Pliocene, about 6 million to 2 million years ago. After the Rocky Mountains were built by the Laramide Orogeny, the area was uplifted, draining the great Cretaceous seas that covered the central United States. The older Permian, Triassic, Jurassic, and Cretaceous rocks were exposed at the surface and subject to extensive weathering and erosion as large rivers began draining the eastern slopes of the Rocky Mountains. These rivers flowed eastward, carving deep valleys and channels into the preexisting rocks and sediment. Strong winds also carried significant amounts of sediment off the mountains and into the plains below. The earliest deposits are gravels and coarse sands in the base of the river valleys, but coalescing aprons of sediment covered the entire eastern base of the mountains, and braided streams formed a large depositional plain across the western edge of the Great Plains. Sediments covered the entire area and reached a maximal thickness of 900 feet (274 m). In the northern High Plains, the Ogallala Formation is divided into three members (subdivisions), named the Valentine, Ash Hollow, and Kimball, for the fossil vertebrates and plants that they contain. These subdivisions are unrecognizable to the south.

The basal gravels that fill the old river channels range from boulder to pebble size and are mostly composed of quartz, quartzite, chert, and caliche with lesser amounts of limestone. The overlying sands are tan to reddish and are generally finer (smaller) to the east. The sand is locally interlayered with thin shale layers, but they are minor. There are also small zones where the sand has been cemented with calcite and gypsum less frequently, and there are caliche horizons as well. In Texas, caliche is so well developed that it forms an impermeable caprock both on the Ogallala and on succeeding depositional units. In Texas and New Mexico, the gravels that fill the old valleys are similar to the rest of the Ogallala Formation, but much of the overlying sand is wind-blown, indicating arid, aeolian conditions. This is supported by the presence of evaporates and caliche. Fine windblown material called loess is far less permeable than fluvial sands.

#### **WATER CAPACITY, PRODUCTION, AND QUALITY**

The Ogallala Aquifer contains an immense amount of groundwater. The water-saturated thickness of the aquifer ranges from a few feet to an estimated 525 feet (160 m). In general, the thicker water-bearing section is in the northern plains, with the saturated zone in the southern plains ranging from 50

**The Ogallala Aquifer stretches for 800 miles (1,300 km) through South Dakota, Wyoming, Nebraska, Colorado, Kansas, Oklahoma, Texas, and New Mexico.**

feet (15 m) to 200 feet (61 m) at maximum. Depth below the surface to this saturated zone ranges from 400 feet (123 m) in parts of the northern plains to approximately 100–200 feet (30–61 m) through most of the southern plains.

The quality of the water is variable. Dissolved solids range from about 0.03 ounce per gallon (250 mg/L) of water to more than 0.13 ounce per gallon (1,000 mg/L) locally, with the vast majority of measurements below 0.07 ounce per gallon (500 mg/L). Crops can tolerate water with dissolved solids below 0.07 ounce per gallon (500 mg/L) but may experience problems with higher concentrations. The principal dissolved solid north of the Arkansas River is sulfate from gypsum weathered out of Upper Cretaceous rock directly beneath the aquifer. This area contains the highest levels of dissolved solids. South of the river, the main dissolved solids are calcium-magnesium bicarbonate. Where there is hydraulic interaction with the underlying units, there is local input of

mineralized waters that degrade the water quality of the aquifer.

Pumping of water from the Ogallala Aquifer began in the 1800s using windmill powered pumps, but large-scale withdrawal did not begin until after the great drought of the 1930s. By 1949, up to 10 percent of the land, or 2.1 million acres (850,000 ha), overlying the aquifer was irrigated. By 1980, the irrigated area was up to 13.7 million acres (5.54 million ha), and, by 1990, it was 13.9 million acres (5.63 million ha). Annual withdrawal of water from the aquifer has exceeded recharge since the 1960s. The height of the water table in the Ogallala Aquifer has decreased up to 175 feet (54 m) in some areas, with an average of 100 feet (30.8 m). The rate of decline ranges from 1.4 feet (0.4 m) per year to 1.7 feet (0.5 m) per year at most, but it is actually rising in other areas. The rapid drop in water level has changed the Arkansas River from effluent to influent. Whereas the Ogallala and overlying aquifers previously fed the river from springs, between 1995 and 2000, the average aquifer recharge from the river was 100,000 acre-feet ( $1.2 \times 10^8 \text{ m}^3$ ) in Kansas. During dry years, the Arkansas River can dry up. The Canadian River and South Platte River are still effluent, but they are receiving less groundwater recharge every year. At the current rate of decline of the water table in the aquifer, they will reverse to influent rivers as well. Even land under canals and land irrigated with diverted river water is now recharging the aquifer in many areas.

The largest loss of water in the area above the Ogallala Aquifer occurs through evaporation. This process tends to concentrate ions and contaminants in remaining water. With all of the irrigation comes excessive use of fertilizers and pesticides to improve crop output. Instead of a few aquifer recharge zones in areas of coarse sand at the base of the mountains, aquifer recharge is much more widespread. With the degradation of surface water quality and increase in infiltration, the quality of the water in the Ogallala Aquifer is expected to decrease even further in coming years. This excessive loss of water and threat to the health of the Ogallala Aquifer is such that the U.S. Congress is considering bills to regulate water use in this area.

**oil spills** As our energy needs increase, humans use ever-increasing amounts of oil. To produce such vast quantities of oil at such a fast rate requires complex technology with ever-increasing handling capacities. High volume and rate technology can be an economic boon to producing areas, but even small mishaps can result in disastrous oil spills that devastate the environment. The oceans typically suffer the most environmental degradation from oil spills. By far the two most spill-prone operations in the ocean are drilling and producing offshore oil wells and fields and transporting the oil in tankers and super-tankers. There are many other sources of oil entering

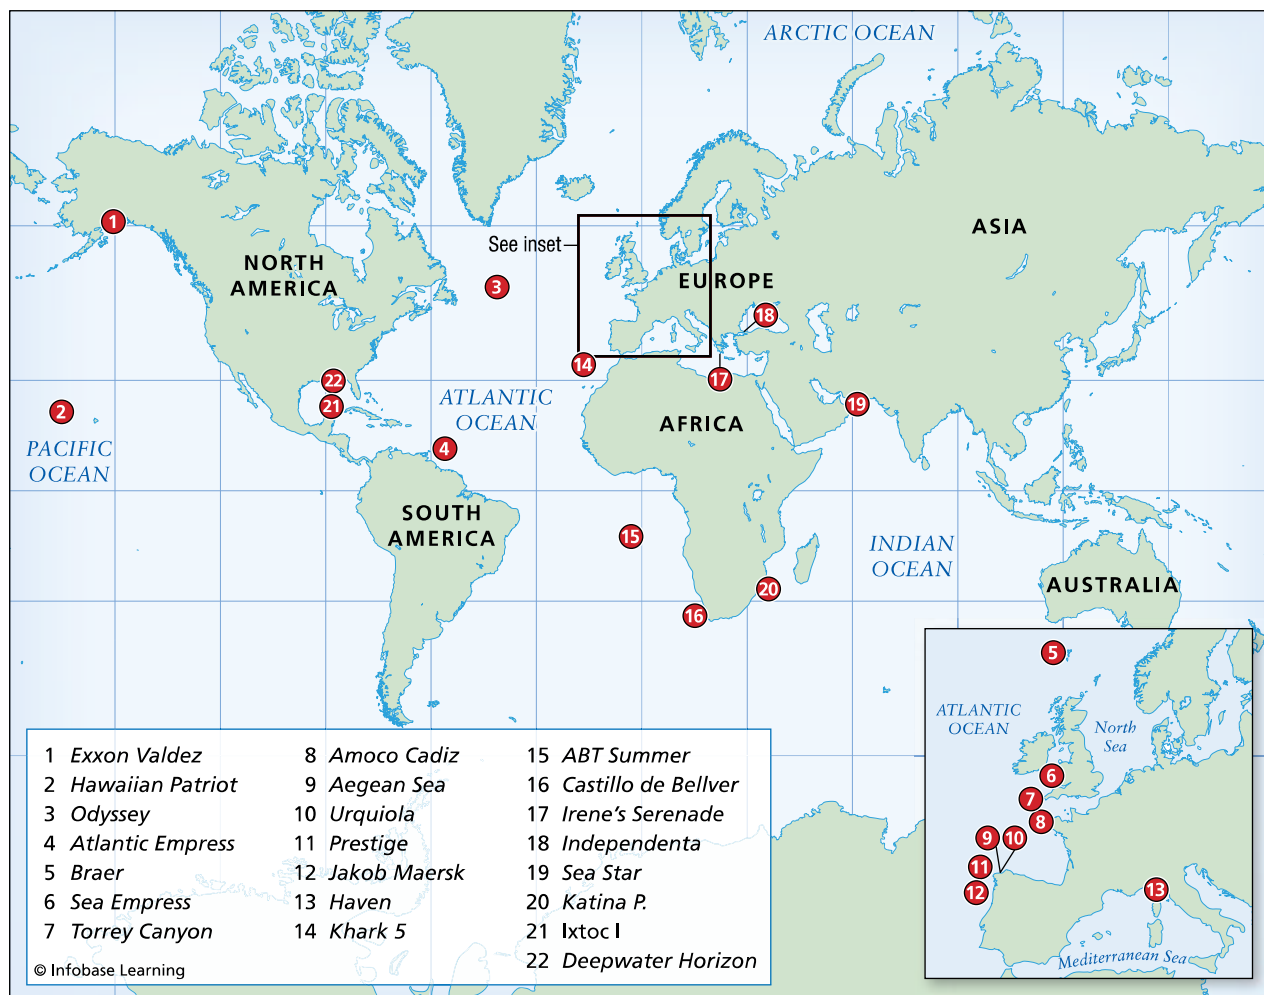

the ocean ranging from boats to surface runoff, but the volume from these is far smaller.

Recent studies indicate the average discharge of oil into the oceans and navigable waterways is 42.7 million gallons (161.6 million L). This average does not include the several years of megaspills of 125–335 million gallons (473–1,268 million L). The megaspill years include, in decreasing order, 1991, 2010, 1979, 1983, 1978, and 1980. The frequency of these megaspill years has decreased recently as a result of greatly improved safety procedures and devices, although an event may occur at any time but especially during natural disasters. Typically, a single incident defines a megaspill year.

Oil spills from grounded and damaged tankers or from accidents during transfer of oil to a storage facility commonly occur in coastal areas. They cause severe environmental damage and loss of marine life on beaches and especially in estuaries, which are ecologically sensitive. They also have an economic impact in direct cleanup costs, beach closings and other recreation losses, damage to sport fish and bird populations, and diminished

Oil well being installed near Fort Lupton, Colorado, 2006 (Rick Wilking/Reuters/Landov)

**Map of the world showing the locations of select oil spills from both tankers and blowout of oil wells (Many of the spills are described in this book.)**

property values. Oil spills from platforms may also be close to shore or in deeper water. Coastal spills from platforms present essentially the same problems as those from tankers. Deep-water spills do not directly affect shore communities or coastal marine and bird life. It is difficult to assess the effect of oil spills on deepwater marine life because it cannot be observed directly.

Americans became acutely aware of the potential damage from oil platform spills when a Union Oil well suffered a gas blowout on January 29, 1969, in the Santa Barbara Channel, California. The well was quickly capped but built-up pressure forced oil from the seabed for 11 days. In total, some 200,000 gallons (760,000 L) was spilled, covering 800 square miles (2,048 km<sup>2</sup>) and killing 3,600 shore birds and innumerable fish, dolphins, and seals. It was not a large spill, but its visual impact on American television is credited to have fueled the environmental movement into a position of prominence.

The June 3, 1979, blowout of the Ixtoc I well in the Campeche area of offshore Mexico was the largest spill of all time of any kind, with an estimated loss of 140 million gallons (532 million L). The April 20, 2010, blowout of the *Deepwater Horizon* in the Gulf of Mexico was even larger, with 204 million gallons (775 million L) spilled. Both of these spills are dwarfed by the mammoth spill that began in January 1991 in the Persian Gulf during Operation Desert Storm. Considering that so much of the world's oil is from the Persian Gulf and is shipped out by tanker, regular oil spills are a way of life. It is estimated that, on average, 230,000 gallons (950,000 L) of oil is spilled into the Persian Gulf through routine operations per day. As a result, it has been called one of the world's most polluted water bodies. The eight-year Iran-Iraq War involved the regular bombing of oil production facilities and greatly increased the annual average of spills during that period. One damaged

oil rig poured out 54,350 gallons (205,737 L) of oil per day for three months.

Despite the tremendous amount of oil spilled on a regular basis in the Persian Gulf, the catastrophic event of the Gulf War was required to make the problem so prominent. It is estimated that 252.8 million gallons (957 million L) was spilled through a combination of sabotage of the fields by the Iraqis, bombing, and a major battle site at a refinery. The oil slick covered some 350 miles (570 km) of the Saudi Arabian coastline and would have been much larger were the waves and currents in the Persian Gulf not so small. Nonetheless, oil spill experts from United States, Great Britain, Netherlands, Germany, Australia, and Japan rushed to the area and managed to protect the input pipes at desalination plants and refineries, though marine life was strongly affected. It is estimated that half of the oil evaporated, 94.8 million gallons (359 million L) was recovered, and the rest sank to the bottom of the Persian Gulf.

Tanker and transfer accidents can also produce devastating effects. As tankers were built ever larger to carry ever-increasing amounts of oil, the impacts of accidents have become increasingly devastating. The first ultralarge tankers, called supertankers, were developed in the late 1960s, and the first accident with a supertanker was the *Torrey Canyon* spill of March 18, 1967. The tanker hit some rocks off the southern coast of the United Kingdom and inundated the coast with oil. The effect on sea life and coastal communities was devastating and exacerbated by ill-conceived cleanup strategies by the military.

Just 11 years later, on March 16, 1978, the *Amoco Cadiz* ran aground on the English Channel side of the United Kingdom and broke up on the rocks, spilling some 66.4 million gallons (251 million L) of oil into the channel. Gale force winds and a particularly high tide spread the spill over more than 180 miles (300 km) of French coastline. In all, some 3,000 birds died, and oyster farms and fishing suffered greatly.

The United States has not escaped the devastation of a tanker accident and spill. The March 1989 grounding of the *Exxon Valdez* is the most famous of these, though the volume of the spill is much smaller than that of many others. The tanker hit a reef in Prince William Sound, tearing a large gash in the hull and spilling 35,000 tons (10.8 million gallons [40.8 million L] or 31,818 metric tons) of oil. The effect of the spill was greatly exacerbated by the remoteness of the area, strong tidal currents, rugged coastline, and severe weather. The spill spread quickly to cover more than 900 square miles (2,300 km<sup>2</sup>) and caused great damage to the fragile arctic ecosystem. By 1992, 13 percent of the spill had settled into the sediments, 2 percent was on beaches, 50 percent degraded naturally into the water, 20 percent evaporated, and 14 percent was recovered and removed.

Although the technology to produce, transport, and use large quantities of oil has been developed, the capacity to clean up spills or even to understand the best course of action lags woefully far behind. On average, only 8–15 percent of spilled oil is recovered, and that includes the mixed-in seawater. The methods for containment and removal are purely mechanical and include oil booms and oil skimmers, respectively. The booms surround the spill and prevent it from spreading. The most common skimmer is a catamaran with a moving belt. The oil adheres to the belt and is lifted into storage tanks. The methods are somewhat effective in protected areas, if the weather is good, but ineffective in all other conditions.

Onshore cleanup methods are typically more damaging to the environment than the spill itself. The initial spill is very damaging to marine life that cannot escape and to birds, depending upon the season. Oil flattens feathers and reduces the birds' resistance to cold. Oil can clog the fishes' gills and slowly suffocate them and can similarly clog filter feeders. Once it begins to thin, however, it is less dangerous, as the toxicity of weathered crude oil is relatively low. It is at this point that the cleanup teams typically arrive. They use harsh dispersants and detergents that commonly kill more wildlife

**Graph of total tonnage of oil spilled from tanker accidents versus years (time) from 1970 to 2006**

than the oil. Hot water is sprayed onto the beaches with high-pressure hoses (100 psi or 6.8 bars) that stream barnacles, snails, and other animals that cling to the rocks. They cause excessive erosion of the beach and drive the oil deeply into the sediments where it is less prone to evaporation. The other common method is to spread hay on the beach to soak up the oil and then rake it off. All of these procedures involve numerous vehicles, heavy equipment, hoses, camp sites, and scores of people trampling through the already-damaged area.

Recent studies indicate that the best method to address oil spills is to prevent them from reaching the shore in the first place. Spraying them with low-toxicity dispersants and developing more effective physical barriers are two recommended strategies. The addition of nutrients to the beaches to increase the microbial populations that hasten the breakdown of oil and the addition of oil-degrading strains of bacteria to the area are also under evaluation. It is fortunate that we transport oil in its crude form because refined forms, such as gasoline and diesel, are far more toxic.

**Omaha lead site Omaha, Nebraska (1987–present)** *Air and Soil Pollution* The 23-acre (9.3-ha) ASARCO lead processing facility in Omaha, Nebraska, left a legacy of soil contamination that local residents and environmental regulatory agencies are still struggling to overcome. Formerly the American Smelting and Refining Company, ASARCO is a copper and minerals production company headquartered in Arizona and owned by

Grupo Mexico, the third largest copper producer in the world. Between 1871 and 1997, at 500 Douglas Street along the west bank of the Missouri River on the eastern edge of downtown Omaha, ASARCO and its predecessor companies processed lead ore that contained economically recoverable concentrations of gold, silver, antimony, and bismuth by using a pyrometallurgical process.

#### OPERATIONS OF THE PLANT

Concentrated lead ore was received at the ASARCO plant in Omaha and then calcined by roasting and mixed with charcoal and a flux of limestone. This mixture then was melted in a blast furnace to separate the lead from other impurities in the ore. Compounds of the impurities floated to the top of the molten metal as slag and were physically separated from the purified lead concentrate, called bullion. Depending upon the level of purity required, the process was repeated a second or even third time to ensure removal of all but trace levels of impurities. The “impurities” in the lead were actually valuable commercial and industrial minerals such as gold, silver, and bismuth. The recovered slag, which was collected and sent for refining, often had a greater value than the lead bullion. At the Omaha plant, final products included finished lead, as well as specialty metal by-products such as antimony-rich lead, bismuth, dore (a mixture of gold and silver in cast bars), and antimony oxide. Refined lead was shaped into 100-pound (45.4-kg) cylinders or one-ton (0.91-metric-ton) blocks that were then shipped to ASARCO customers.

#### POLLUTION OF THE SITE

Each time the ore was heated, waste materials were generated in the form of lead- and sulfur-enriched dust and fumes. In today’s modern mineral processing plants, air pollution control devices such as baghouses and scrubbers collect the vast majority of these dusts and fumes, and they are either reused in the process to make sulfuric acid and other economic compounds or disposed of in accordance with local waste management regulations or plant permit requirements.

During the majority of the facility’s operational life, the air pollution control devices were minimal, and, as a result, dusts enriched with lead and other metals were discharged into the atmosphere through smokestacks and process vents. These dusts were carried by the prevailing winds and settled onto the ground in residential neighborhoods and commercial areas throughout Omaha.

In 1987–1997, the ASARCO Omaha facility released 400 tons (362.9 metric tons) of arsenic, lead, chlorine, and numerous other types of toxic materials into the atmosphere. Similar releases to the water (40 tons, or 36.3 metric tons) and soil (17 tons, or 15.4 metric tons) also took place during this period. In 1992, in large part because of releases, the air quality surrounding the plant was found to be in nonattainment for lead in terms of the Clean Air Act. This allowed the U.S. Environmental Protection Agency (EPA) to require that stringent and expensive air pollution control measures be implemented at the ASARCO facility. In 1995, rather than installing the almost \$40 million worth of air pollution control equipment needed at the plant, ASARCO announced that the Omaha facility would be closed. Final shut-down including demolition was completed in 1999, and plant grounds have been decontaminated and the site redeveloped by the city of Omaha for commercial and recreational uses.

A second lead smelter operated in Omaha from the early 1950s until 1983. Located only about 500 yards (457.2 m) west of the ASARCO plant, the Gould Electronics facility also smelted and recycled lead. This facility was a major contributor to atmospheric lead within the city. It, too, was torn down and the area reclaimed as a county park. Several other businesses within the city also used lead in manufacturing processes, but none was close to matching the quantities emitted by the ASARCO and Gould facilities. Some of the lead reported in soil in Omaha is probably related to lead-based paint and automobile exhaust from the former (pre-1986) use of leaded gasoline.

A year-long study conducted by the Douglas County Health Department screened blood lead levels in 2,800 children and found that almost 600 had lead levels of 10 micrograms per deciliter (mcg/dL) or higher. Research data indicate that concentration of lead in blood in excess of 10 mcg/dL in young children can impair intellectual development and cause reading and learning disabilities, impaired hearing, reduced attention span, hyperactivity, and antisocial behavior. As the extent of lead in soil, especially in residential areas, became known, local city government asked the EPA for assistance in identifying and remediating the problem.

### REMEDIATION OF THE SITE

Working under authority granted by the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), the EPA and its contractors added the properties to the National Priorities List as a Superfund site on April 30, 2004. They

defined the Omaha Lead Site through historical records, soil sampling at 22,000 residential properties, and public health data that include contaminated surface soils at residential properties, child care facilities, schools, and other residential-type areas within the city of Omaha. These areas, some as far as 2.5 miles (4 km) from the ASARCO plant, were impacted by air emissions from lead smelting operations. The Omaha Lead Site encompasses an area of approximately 8,800 acres (3,561 ha) and includes approximately 65,600 residents living within the identified contaminant zone. There are also 20 Omaha public schools with an enrollment of 11,700 students surrounded by lead-contaminated soil, and 240 child care facilities within a three-mile (4.8-km) radius of the center of the site along with parks, golf courses, wetlands, and other public recreational facilities.

Using blood lead levels to prioritize its response actions, the EPA first removed contaminated soil and replaced it with clean fill and grass sod at those schools, child care facilities, and private residences where blood lead concentrations in children were equal to or greater than 10 mcg/dL and where soil samples contained lead concentrations greater than 400 mg/kg. Removal actions were completed at 300 properties, not including the schools and child care facilities, which were addressed first, and action at 5,200 more is planned. Building interiors are also being sampled for lead dust; if they are above recommended levels, they are being cleaned. Lead in soil at nonresidential areas will be chemically stabilized and covered to reduce the possibility of human exposure. Costs for these cleanup activities are estimated at about \$80 million. By mid-2004 the EPA had spent almost \$13 million of public money to perform investigation and remedial activities.

ASARCO is implicated in more than 20 Superfund sites and has estimated environmental liabilities of more than \$500 million. In August 2005, ASARCO filed for bankruptcy, citing as one of the reasons the more than 100 environmentally related lawsuits and enforcement actions for which the company was being held responsible. As part of bankruptcy proceedings, ASARCO established a \$100-million trust fund with USEPA approval to be used solely for environmental cleanup. Some \$3 million from that trust fund was allocated to the Omaha Lead Site. It is interesting to note that just before declaring bankruptcy, Grupo Mexico, ASARCO's parent company, transferred a large portion of ASARCO's assets to a separate offshore holding company.

**opacity** One effect of particulate emissions is an increase in atmospheric opacity. As sunlight is blocked by a medium such as smoke or the tinted windows of a car, its opacity increases. Opacity is measured as a percentage; 0 percent opacity indicates that the medium through which light is passing has no effect on its transmission in the visible light spectrum. In contrast, an opacity of 100 percent indicates that no light is able to pass through the medium. Opacity, the amount of light blocked by a medium such as smoke, provides an indication of the concentration of particulate being discharged from a vent or smokestack. The higher the particulate concentration, the more light that will be blocked, and the higher the opacity will be.

Today, particulate emissions are measured by sophisticated devices called transmissometers. These instruments measure the amount of a known quantity of light that is able to pass through smoke. Transmissometers consist of a light source attached to one side of a smokestack or exhaust vent and a selenium photocell attached to the opposite side. The photocell is covered with an optical filter that measures the quantity of light it receives and matches it to the spectral response of the human eye. A zero reading from a transmissometer means 0 percent opacity or 100 percent transmission. It is the output recorded when the light is on and no smoke is present.

In the early 1900s, local and state health departments struggled with a way to measure particulate air emissions and to enforce nuisance laws related to the release of soot and ash. It was difficult to make a case because of the subjective nature of the observations. The definitions of heavy smoke, dense smoke, and so on, were too variable for many courts to feel very confident that they were treating the accused

in a fair and even-handed manner. This changed around 1910, when the Ringelmann chart began to be widely accepted as a way to measure opacity.

Maximilien Ringelmann was a French engineer, who, in the late 1800s, noticed that the amount of black smoke produced by a boiler was related to its combustion efficiency, or air-to-fuel ratio. Ringelmann thought that if the darkness (opacity) of the smoke could be reliably measured, it could be used to help adjust the combustion efficiency of the boiler. He designed a series of black grids on a white background that he placed 50 feet (15.2 m) away from the smokestack of the boiler. Ringelmann then compared the color of the smoke with the color on the grid and was able to adjust the air/fuel ratio in the boiler reliably to reduce the opacity of the smoke. In the early 1900s, the U.S. Bureau of Mines approved the Ringelmann chart for measuring smoke emission at coal mines. One Ringelmann meant the smoke had an opacity of 20 percent, or was blocking 20 percent of visible light. Two Ringelmanns meant that 40 percent of the light was being blocked for an opacity of 40 percent. With this semiquantitative, less subjective method now available, by 1920, municipalities throughout the United States had adopted the Ringelmann chart as an inspection and enforcement tool to control nuisance smoke.

Even though transmissometers are in wide use at most industrial and power generating facilities, human observers still play an important role in the monitoring of particulate emissions and the enforcement of air quality regulations. The Ringelmann scale has been replaced by a set of standardized specifications and procedures described in the U.S. Code of Federal Regulations. Individuals can be certified as visual emission observers by passing a rigorous training program at a qualified "smoke school." Those seeking certification must be able to estimate, within a certain percentage of accuracy, the opacities of 50 different types of black and white smoke. Visual emission certification is valid for only six months at a time, and smoke school training must be repeated twice a year to maintain certification. Once certified, visual emission observers are able to estimate the percentage of opacity of smoke being emitted from a stack or exhaust vent. This determination is legally enforceable and can serve as the basis for fines and other regulatory enforcement actions. Opacity observations are used regularly by the U.S. Environmental Protection Agency (EPA) and many state environmental programs as a quick and easy way to evaluate the effectiveness of a facility's air emission control program and to take enforcement action

when visual observations indicate acceptable levels are being exceeded.

**organic pollutants** Pollutants can be generally categorized as organic or inorganic. Organic pollutants are overwhelmingly produced through biologic activity, although some can also be produced as a result of volcanic eruptions. They are compounds of hydrogen and carbon (hydrocarbons) in various bonding configurations and, in many cases, bonded to other elements as well. The most dangerous of the organic pollutants are derivatives of petroleum. Some of these derivatives are directly from distillation of petroleum and generally used as fuel or solvents. The remaining organic pollutants are dominated by chemically altered petroleum derivatives.

There are several overlapping classification schemes for organic pollutants, primarily based on their physical and chemical properties. The primary division for organic pollutants is whether or not they are prone to evaporation. Compounds that evaporate easily are volatile and generally fall into the category of volatile organic compounds (VOCs). The volatility of a compound is determined by its vapor pressure, which is the pressure exerted by the vapor in equilibrium with its condensed liquid in a sealed container. If a compound has a high vapor pressure, it evaporates more quickly than a compound with a low vapor pressure. VOCs have vapor pressures such that they readily evaporate under pressures and

temperatures of the Earth's surface and accumulate in the atmosphere.

As a subcategory of direct volatility, compounds that are dissolved in water may also be released into the air. The tendency of a dissolved compound to partition from the water to air is quantitatively known as Henry's constant (H). Just like direct volatility, it is a function of the vapor pressure of the compound but also its solubility in water. High H favors evaporation, and low H favors the compound remaining in the water.

Organic compounds dissolved in water can also partition between water and sediment at the base of streams and lakes. If a compound has a tendency toward being hydrophobic (dislikes water), it will be removed from the water and become fixed or sorbed onto the sediments, depending on the physical and chemical conditions. The measure of this tendency is the distribution or partition coefficient (Kd), which is greater for compounds that remain dissolved. As conditions change, the compound may desorb and be released back into the water. This fixing and releasing of compounds in soils and sediments slows the movement of the pollutant. The ratio of the velocity of the water to the velocity of the pollutant is called the retardation factor.

Another physical property that is used to classify organic pollutants is density. Compounds that do not readily dissolve in water are termed *nonaqueous phase liquids* (NAPLs) in the environmental industry. If a NAPL has a density less than that of water (1.0 g/ml), it will float on top of groundwater and surface water in the natural environment. Such compounds are light nonaqueous phase liquids (LNAPLs). If a NAPL has a density greater than that of water, it will sink through groundwater and surface water. Such compounds are dense nonaqueous phase liquids (DNAPLs).

#### PETROLEUM

The main source of organic pollutants is petroleum, whether directly from the crude oil source or from the synthetic organic compounds into which it is manufactured. The ultimate source of crude oil is plankton and biologic by-products in the oceans. When plankton die, they settle with the other organic material and clay to areas of low wave and tide energy, such as lagoons, bays, and the deep oceanic plains. With time, this organic material is buried under thick sequences of sediment that heat and pressurize it. The changing physical and chemical conditions convert the organic material first into kerogens and later into oil and natural gas through a series of chemical reactions. These liquid and gas-

eous hydrocarbons migrate into geologic features called traps, where they can accumulate for an indefinite period of time, typically millions of years.

Crude oil is almost exclusively obtained from the petroleum traps through drilled oil wells. The only other way that it reaches the surface is through seeps or tar pits, but the amount is very minor and it flows so slowly that, in most cases, it can be broken down and removed by natural processes. Crude oil is composed of 83–87 percent carbon, 10–14 percent hydrogen, up to 6 percent sulfur, up to 2 percent nitrogen, up to 1.5 percent oxygen, and less than 1,000 parts per million of assorted metals. The compounds of crude oil are a mixture of numerous hydrocarbon types in various proportions. These hydrocarbons are classified into several chemical forms, including paraffins or alkanes, naphthenes or cycloalkenes, aromatics, and asphaltics in order of increasing density and thickness.

Crude oil is commonly classified by its density or gravity using the American Petroleum Institute (API) scale. API gravity is measured in degrees using the formula:

$$(141.5/\text{Specific Gravity of the oil}) - 131.5 = \text{API Gravity}$$

Crude oil that is capable of flowing is classified as light, medium, or heavy using this number. Light oil has an API gravity greater than 31.1° and a high paraffin to naphthene plus aromatic ratio. Medium oil has an API gravity ranging between 22.3° and 31.1°. Heavy oil has an API gravity less than 22.3° and a high aromatics plus naphthenes to aromatics ratio. Crude oil that cannot flow without being heated or diluted is called extra heavy oil or bitumen. It has an API gravity of less than 10° and is composed primarily of polycyclic aromatics and asphaltics. This oil is commonly chemically “upgraded” to an API gravity of 31° to 33° and classified as synthetic crude oil.

In addition to API gravity, crude oil is also generally classified by its sulfur content. Sweet oil has a low sulfur content, whereas sour oil has a high sulfur content. Combining these two measures, traditionally, crude oil is classified by its location and used as a benchmark for trading. West Texas Intermediate (WTI) is a benchmark crude oil that is very light, sweet high-quality oil. Brent Blend is another benchmark that is a mixture of 15 crude oils from fields in the Brent and Ninian systems of the North Sea oil province. It is also high-quality light oil with a low sulfur content. The OPEC Reference Basket is a weighted average of oil blends from all of OPEC (Organization of the Petroleum Exporting

Countries), including Saudi Arabia, Qatar, Libya, Algeria, Dubai, Indonesia, Nigeria, Malaysia, and others. Included in OPEC is Arab Light, a light sour oil from Saudi Arabia; Tapis, from Malaysia and the reference for light Far East oil; Minas, from Indonesia and the reference for heavy Far East oil; Bonny Light oil from Nigeria; Saharan Blend from Algeria; and Tijuana Light from Venezuela, among others.

The U.S. Environmental Protection Agency (EPA) has another system to classify crude oil that has been released to the environment in a spill response scenario.

- **Class A: Light, Volatile Oils** are highly fluid, commonly clear oils that spread on water, have a high evaporation rate, a strong odor, and are usually flammable. They include most refined hydrocarbon products (distillates) as well as the highest quality crude oils. Class A oils penetrate soil and sand and may persist there under certain conditions but are easily removed with water. They may be toxic to humans, fish, and other biota.
- **Class B: Non-Sticky Oils** are waxy and oily. They include medium to heavy paraffin crude oils. Class B oils adhere firmly to surfaces but may be removed through vigorous flushing. Normally, they do not penetrate sand and soil well, but as temperatures rise penetration increases, as does persistence. They are less toxic than Class A oils, but evaporation from volatiles from Class B oils forms residues of Class C or D oils.
- **Class C: Heavy, Sticky Oils** are tarlike, sticky, and black to brown in color. They include residual fuel oils and medium to heavy crude oils. If left to evaporate, they produce class D oils. The oil does not easily penetrate porous materials, but it is nonetheless difficult to remove. It is heavy and can sink in water in some cases. These oils are not particularly toxic, but they can smother wildlife.
- **Class D: Nonfluid Oils** are black to brown and tarlike. They include residual oils, heavy crude oils, and high-paraffin oils. They do not penetrate porous materials, but, if heated, they melt onto surfaces and are very difficult to remove. Class D oils are relatively nontoxic.

Crude oil is refined into common petroleum products, including fuels, at an oil refinery. Primary refining is done through distillation in a distillation tower. The crude oil is heated at the base of the tower until it vaporizes. The vapor stratifies in the tower by its density, the lighter organic compounds floating to higher levels. It is condensed at several levels and collected as separate products: jet fuel at the top, diesel and gasoline in the middle, and tar at the bottom. These primary products may be modified into the other petroleum products as needed, using chemical catalysts. These catalysts may be used to break long hydrocarbon chain molecules into shorter ones (cat cracking) or they may be used to combine short chains into longer ones.

### FUEL OIL

Fuel oil is a product from the refining of crude oil. In strict terms, fuel oil is liquid petroleum that is used in an engine to generate power or in a furnace to generate heat. However, it typically only refers to the heaviest commercial fuels and does not apply to gasoline or other light fuels. The classification of fuel oil is in six grades based upon boiling point, composition, viscosity, and use. The oils are heavier and thicker for higher grades. Grades 1 and 2 are called distillate fuel oils whereas grades 4, 5 (light), 5 (heavy) and 6 are termed residual fuel oils (RFO).

- **Grade No. 1 fuel oil** is a light distillate that is similar to kerosene and slightly heavier than gasoline. It is highly volatile and used in vaporizing-type burners.
- **Grade No. 2 fuel oil** is diesel fuel used in trucks, cars, and some trains and is sometimes called road diesel. It is also called heating oil because it is the fuel used in home furnaces as well as many commercial-industrial burners. There is a dewaxed version of grade no. 2 available that is used in cold areas where regular grade no. 2 fuel oil would jell. It can be referred to as Bunker A fuel or marine gas oil (MGO).
- **Grade No. 3 fuel oil** is a distillate fuel that is rarely used.
- **Grade No. 4 fuel oil** is an intermediate fuel that can be a blend of distillate and residual fuel oils or just be a heavy distillate/light residual. It is too heavy to be used in home furnaces. It is sometimes referred to as Bunker B fuel.
- **Grade No. 5 fuel oil** is divided into light and heavy, depending on the climate in which it is to be used. It has an intermediate viscosity but still may require preheating in colder climates before it can be burned or even handled. It is also called Bunker B fuel or navy special fuel oil.
- **Grade No. 6 fuel oil** is an RFO that is sometimes called Bunker C, furnace fuel oil (FFO), heavy fuel oil (HFO), or marine fuel oil (MFO). It is mostly used in industrial heating but requires heating before pumping or burning.

Fuel oil is spilled into the ground surface and marine environments on a regular basis through normal handling as well as spills. Most shipping and boating accidents also involve the release of fuel oil into marine environments. The EPA classification for spilled crude oil also includes fuel oil, primarily as to their distillate or residual origins.

### VOLATILE ORGANIC COMPOUNDS (VOCs)

Any organic compound with vapor pressure that exceeds 0.002 pounds per square inch (0.133 mbar or 0.1 mm of Hg) at standard temperature and pressure is considered a VOC. They are characterized by low molecular weights, high vapor pressures, and a hydrophobic nature. They are commonly in the form of liquids and gases but rarely solids as well. Their volatility makes them very common atmospheric pollutants but less likely water and soil pollutants. The most common health effects from exposure to VOCs are eye and throat irritation, headaches and dizziness, nervous system damage, exacerbation of asthma and COPD (chronic obstructive pulmonary disease), and possible cancer.

Massive amounts of VOCs are constantly being released to the atmosphere through industrial processes and even regular human activities. Crude oil and fuels readily evaporate whenever exposed to the air. Solvents in paints and other surface coatings, as well as those used for cleaning, evaporate into the atmosphere as well. The inundation of the atmosphere by VOCs is not only a problem in itself, but VOCs also participate in a photochemical reaction with nitrogen oxide to produce low-level ozone, one of the most damaging air pollutants. Recent regulations limit the amount of VOC in household products because of the direct health effects. Considering the amount of VOC in the atmosphere today in comparison with the atmosphere of the past that contained essentially no VOCs, there may be more

### CHARACTERISTICS OF FUEL OIL

Grade No.	API Gravity	Density lb/gal	Higher Heating Value Btu/gal
1	38–45	6.950–6.675	137,000–132,900
2	30–38	7.296–6.960	141,800–137,000
4	20–28	7.787–7.396	148,100–143,100
5 (light)	17–22	7.940–7.686	150,000–146,800
5 (heavy)	14–18	8.080–7.890	152,000–149,400
6	8–15	8.448–8.053	155,900–151,300

dangerous effects that have yet to be realized. Common chemical groups of VOCs include alkanes, alkenes, aryl hydrocarbons, aldehydes and ketones, alcohols, epoxides, carboxylic acids and phenols, ethers, halogenated hydrocarbons, and nitrogen-containing organic compounds.

#### SEMIVOLATILE ORGANIC COMPOUNDS (SVOCs)

A semivolatile organic compound (SVOC) is an organic compound that has a low to moderate vapor pressure, so it can vaporize like a VOC but only at elevated temperatures. They have boiling points greater than that of water. SVOCs are hydrophobic and preferentially distribute to organic materials such as organic carbon in sediment and lipids (fat) in animal tissue. For that reason, they tend to bioaccumulate in animals and humans, but not to the degree of many other compounds, such as persistent organic compounds. Bioconcentration factors for SVOCs are typically between 10 and 1,000. This bioconcentration means that consumption of seafood and even some meats and homegrown vegetables can form ingestion pathways for SVOCs as can incinerator emissions, contact with contaminated soils and sediments, and contact with waste materials.

There are many SVOCs, including the numerous polycyclic aromatic hydrocarbons (PAHs), phenols, halogenated compounds, phthalates, azaarenes, nitrogenated compounds, and cyclic ketones, among others. Several of these are regarded as priority pollutants by the EPA and have been banned since the 1970s, named specifically in the Clean Water Act of 1977. Included among these are phthalates, phenols, and PAHs, which are probable human carcinogens and endocrine disruptors.

A long-term study by the U.S. Geological Survey found that SVOCs are nearly ubiquitous in sediments within streambeds of the United States and concentrated in urban areas. The study found that

the Northeast and the Great Lakes regions are particularly enriched. PAHs and phthalates were about 10 times higher in areas influenced by urban activities, and adverse health effects as a result are probable in 7.5 percent of these areas and possible in 16.2 percent.

#### SYNTHETIC ORGANIC COMPOUNDS (SOCs)

Sometimes known as non-VOCs, synthetic organic compounds (SOCs) are high-molecular-weight organic compounds that mostly exist as solids or high-boiling-point liquids (low vapor pressure). SOCs are released from industry or purposefully during regular activities. They enter the natural environment dissolved in precipitation, from fallout or dry deposition, through photochemical reactions, incorporated in particulate matter, and by uptake in plants.

The most dangerous of the SOCs are the persistent organic pollutants (POPs). These chemicals are released by industry or applied to agricultural settings and resist natural breakdown. That is why they are persistent. As a result, they have the ability to be transported long distances both in the atmosphere and in water. In many cases, POPs have been found in areas far from their points of release, such as in arctic ice. They also bioaccumulate and biomagnify through the food chain through this resistance. Bioconcentration factors for POPs range between 1,000 and 100,000, which are among the highest for any compound.

POPs are primarily insecticides, industrial chemicals, and the by-products of manufacturing processes and combustion. These include the most infamous of the insecticides, such as DDT, aldrin/dieldrin, chlordane, endrin, heptachlor, and toxaphene, among others. The industrial chemicals and by-products are equally infamous, including dioxin, PCBs, and furans. These compounds are extremely damaging

to the environment and even to human health. They are possible to probable human carcinogens and damage the kidneys, lungs, pancreas, nervous system, immune system, and endocrine system.

It is for these adverse health effects that there have been several national and international legislative actions to limit or ban several of the POPs. The 1989 United Nations Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal is an international agreement signed by 158 parties as of 2003 that includes POPs in the list of controlled substances. The 1998 Rotterdam Convention on the Prior Informed Consent Procedure for Certain Hazardous Chemicals and Pesticides in International Trade is a succeeding international agreement that had 73 signatories by 2003 and was more specific to controlling POPs. The most direct and effective agreement, however, is the 2001 Stockholm Convention on Persistent Organic Pollutants (POPs) that had 151 signatories by 2003. This convention aims to eliminate or restrict production and use of all POPs and, ultimately, to eliminate accidental releases of industrial POPs, especially dioxin and furans. PCBs are to be completely eliminated by 2025.

### PPCPs AND EDCs

A relatively new group of organic pollutants of concern are pharmaceutical and personal-care products (PPCPs) and endocrine-disrupting compounds (EDCs). Although both have been in the environment for many decades (approximately 70 years), concern for their ubiquitous presence has recently become an area of great interest. The reason for this concern is because recent surveys have found trace levels of EDCs and PPCPs in most public water supplies and many surface waters and private water supplies. Even at trace concentrations, they can have ecological impacts. The problem is that most standard drinking water and wastewater treatments do not remove EDCs and PPCPs. New advanced treatments are being tested to address these shortcomings.

PPCPs are consumer bioactive chemicals, such as prescription and over-the-counter drugs, veterinary drugs, fragrances, cosmetics, sunscreen products, diagnostic agents, and nutraceuticals (vitamins) that have been released into the natural environment. The sources of such waste are human activity, pharmaceutical manufacturing, hospital waste, illicit drugs, veterinary waste, and agribusiness, among others. PPCPs have only been recognized as a threat by the scientific community since the 1970s, when they were found in trace amounts in treated municipal wastewaters. They were only recognized as a problem by the

U.S. government since 2007. The long-term impact of low-level exposure to PPCPs has yet to be determined, but the rapid development of drug-resistant bacteria is certainly exacerbated by their presence.

EDCs are synthetic, and even some natural, compounds that mimic the natural hormones in the endocrine systems of animals. By mimicking these hormones but not serving the required function in the body, they disrupt the homeostasis, reproduction, development, and/or behavior of the animal. There are three major classes of EDCs: (1) estrogenic, which mimic or block estrogen; (2) androgenic, which mimic or block testosterone; and (3) thyroidal, which directly or indirectly affect the thyroid. The primary area of research on the effects of EDCs is in reproduction. It was found that the EDC and pesticide DDT affected reproduction of birds and alligators; tributylins from antifouling paints and PVC pipes impacted marine gastropods; and the herbicide atrazine greatly affected the reproduction of frogs, among many others. Perhaps the most concerning finding, however, is that fish in the released treated water from wastewater treatment plants showed dramatic reproductive problems. This shows that the numerous wastewater treatment plants in the United States and the world are not removing the EDCs. There is no question that humans are being exposed to EDCs.

### MISCELLANEOUS ORGANIC POLLUTANTS

There are also several organic pollutants that have nonindustrial origins. One such pollutant is farm and stockyard waste. In most cases, livestock and farm animals are raised in tight quarters designed to maximize production. These animals are kept in high-density dwellings that result in issues with the disposal of large quantities of animal waste. In many areas, the waste is stored in shallow lagoons on the property. The massive quantity of stored waste is a problem in itself in terms of odor, local soil and water pollution, and disease. During storms, however, these lagoons can overflow and pollute surface water bodies. The waste can cause eutrophication of these bodies as well as spreading disease.

Stockyards are not the only source of such organic waste. Overflowing sewers and septic systems are also sources of high organic pollutants. They cause the same problems as stockyard waste but in a less concentrated manner.

**ozone** There are two types of ozone, good ozone and bad ozone. Good ozone is located in the stratosphere in the range of about 10–30 miles (16–48 km) elevation above the surface of the Earth. This layer is good because it shields the surface from damaging ultraviolet radiation. Bad ozone is located in the troposphere and especially at elevations of less than 10 miles (16 km). It is this bad ozone that is the primary component of smog and the cause of health alerts in many cities around the world, as well as reduction in crop yield. It is also a greenhouse gas, contributing to global warming. Bad ozone can also be beneficial. It helps to cleanse other pollutants from the air such as hydrocarbons, hydrogen sulfide, and carbon monoxide, which would otherwise poison us. It is odd that a single substance can have such opposing functions. This dual ability is based on the chemical properties of ozone.

### PROPERTIES AND FORMATION

Ozone is a pale blue gas with a faint odor. Normal oxygen in the atmosphere is O<sub>2</sub>, and ozone is simply O<sub>3</sub>, but it is much less stable. Ozone was first identified as a compound in 1840, and it has actually

been monitored in Europe since about 1870 with a simple chemical test. It is both naturally occurring and anthropogenic. Ozone is produced by lightning strikes through dissociation and recombination of normal oxygen by the electrical discharge. It is similarly produced during electrical generation at power plants, as well as electrical use in many industrial and residential applications. In general, the more power-consuming the application, the more ozone is produced. This source of environmental ozone, however, is minor in comparison to other sources. The largest source of tropospheric ozone results from a complex series of photochemical reactions among nitrogen oxides (NO<sub>x</sub>) and volatile organic compounds (VOCs).

Nitrogen oxides are primarily produced by the burning of fossil fuels. By far, the primary sources of NO<sub>x</sub> are motor vehicles, with 56 percent of the production, followed by electric utilities and power generation (22 percent); industrial, commercial, and residential fuel combustion, including heating systems (17 percent); and all other sources of combustion (5 percent). VOCs are produced naturally by some trees, but they are primarily anthropogenic. The synthesized VOCs are almost exclusively produced from the refining and use of petroleum and the use of petroleum products. The primary source is the industrial and commercial production and processing of VOCs (50 percent), followed closely by the release of unburned hydrocarbons by motor vehicles, as well as evaporation of fuels (45 percent). The remaining 5 percent is produced by the evaporation of consumer solvents including paints, sealants and coatings, and cleaners. The number of motor vehicles in the United States increased from 142.1 million in 1977 to 189.4 million in 1993, and the burning of fossil fuels on a worldwide basis tripled in 40 years, thereby increasing both VOCs and NO<sub>x</sub>. When these substances that are pollutants in their own right are released into the atmosphere, they can be exposed to sunlight. The heat and ultraviolet radiation drive a complex series of dissociation reactions that ultimately produce ozone. The production is limited by the quantity of the reactants and the amount and strength of solar radiation. Summer months with minimal wind circulation and strong sunshine are the best conditions for ozone formation.

Bad ozone has some practical applications. Being a strong oxidizer, ozone has the capacity to sanitize, deodorize, and sterilize both water and air. Ozone generators sterilize the air in hospitals and purify air in homes in filtration systems. Ozone can remove microorganisms from meat and poultry and even reduce pesticides from fruits and vegetables. Ozon-

**Graph of relative ozone concentration in air versus altitude. The lower, tropospheric ozone is “bad ozone” in smog, and the stratospheric ozone is “good ozone” that filters ultraviolet (UV) radiation from the Sun.**

ated water is used in laundries, hot tubs, aquariums, and fish ponds. Ozone is used to sanitize municipal water supplies, because it leaves no residues, but it must be supplemented with chlorine because the water can support microorganisms after the ozone dissipates.

### ENVIRONMENTAL RELEASE AND FATE

The concentration of ozone in air from natural sources is about 10–15 parts per million (ppm), as measured in 1870. On average, between 1900 and 1970, the air in the United States experienced increases in the levels of ozone precursor NO<sub>x</sub> of 690 percent and of VOCs of 260 percent. As the result of industrialization, several regions of the United States have average concentrations of up to 125 ppm in summer months. It is not only urban areas of the country that have ozone pollution problems. Elevated ozone levels even exceeding those in the cities may extend downwind of these urban areas for hundreds of miles. Elevated ozone levels have been found in the Maine woods and the mountains of New Hampshire and New York. There is a continuous strip from central Virginia to eastern Maine, including the entire states of Connecticut, New Jersey, and Rhode Island, where the ozone levels consistently exceed the U.S. Environmental

Protection Agency (EPA) limits. There are numerous other counties peppered throughout the eastern United States (32 nationwide) that, in 2004, the EPA designated as in “nonattainment.” The states with the most counties in this designation are Pennsylvania, Maryland, Massachusetts, North Carolina, Michigan, Ohio, New York, Indiana, Tennessee, and Georgia, among others. In the West, a large swath of California is in nonattainment, as are the counties around Denver, Colorado; Phoenix, Arizona; and Houston and Dallas, Texas. Seven of the top eight highest-ozone metropolitan areas were in California, led by Los Angeles, in the 2004 ratings. It is estimated that three-quarters of the population of the United States resides in areas with excessive amounts of ozone in the air.

Vegetation is strongly affected by elevated ozone levels. It enters the plants by infiltrating leaves through the stomata during regular gas exchange. Ozone is a strong oxidant and, as a result, causes chlorosis and necrosis of the plants. Some of the symptoms of ozone poisoning include small (less than 0.04-inch [1-mm]) spots, called flecks; 0.08- to 0.16-inch (2- to 4-mm) darkly pigmented patches, called stipples; as well as bronzing and reddening of the leaves. These symptoms typically occur on tops of older and middle-aged leaves, but the severity is dependent upon the plant species. This damage reduces photosynthesis, cellular energy production, and the number of flowers and fruit. In addition to killing the plant directly, ozone may weaken the plant against pests, drought, and disease. Ozone not only damages trees and wild plants, but also damages crops. Research on crop damage from ozone has been carried out for nearly 40 years. It has been shown that dicot species such as soybeans, cotton, and peanuts start to suffer at as little as 20 parts per billion (ppb) of ozone and can have a 40 percent drop in yield at 100 ppb. Tobacco is even more sensitive. Some monocot species, however, such as sorghum and corn, are relatively resistant to ozone and do not show any effects until 60 ppb and even at 100 ppb only suffer a 10 percent drop in yield. Crop losses from ozone damage are estimated at \$500 million per year.

### HEALTH EFFECTS FROM EXPOSURE

Ozone is also toxic to humans, producing numerous adverse health effects. Up to 20 percent of healthy people are much more susceptible to the effects of ozone than the general population. It oxidizes the surface of the respiratory system, causing excessive mucus production and constriction of the muscles. Initial symptoms include coughing, throat irrita-

tion, wheezing, discomfort in the chest, and possible nausea. The National Institutes of Health reported a 5–10 percent reduction in lung capacity of people who exercised for 6.5 hours while exposed to 80 ppb of ozone. With prolonged exposure at high dosage, ozone may cause reduced lung function, aggravate chronic lung diseases and asthmatic conditions, inflame and damage lung tissue, and damage the immune system in the lungs, increasing the likelihood of bronchitis and pneumonia. Chronic exposure to ozone causes permanent damage to the lung tissue, decreased pulmonary function, and, ultimately, premature death. There are five groups of people who are at particular risk from the effects of ozone: people who have respiratory disease, older adults, people who work or exercise outdoors, children, and ozone-sensitive people. Approximately one-third of Americans are in this high-risk group including 27.1 million children and more than 1.9 million children who have asthma. It was found that each increase of 20 ppb of ozone in air was associated with a 63 percent increase in school absence due to illness and an 83 percent increase in respiratory illness. The children at greatest risk are disproportionately members of minority groups.

A recent study in Europe found that during the summer, an increase in ozone of one hour resulted in an increase in the total daily number of deaths of 0.33 percent, of death by cardiovascular failure of 0.45 percent, and death by respiratory failure of 1.13 percent. This study indicates that even short-term exposure to ozone can be deadly.

### REGULATIONS ON HUMAN EXPOSURE

In 1971, the EPA set the limit of ozone in ambient air at 120 ppb averaged over an eight-hour day under the newly enacted Clean Air Act. In 1997, the limit was revised to 80 ppb. For an area to be in compliance, the fourth highest eight-hour concentration in one year, averaged over a three-year period, cannot exceed 80 ppb. In addition, areas cannot exceed 120 ppb for a period of one hour more than once over any three-year period. This new limit made many areas out of compliance. On days when ozone is in excess of the limit or expected to exceed the limit, an Ozone Action Day may be declared, in which restrictions on exposure and vehicle use may be imposed. It is monitored through the state and local air monitoring network stations (SLAMS) and national air monitoring network stations (NAMS), among others. The World Health Organization recommends a maximum of 60 ppb averaged over any eight-hour period for a maximum of 20 days per year. In Canada, the maximal concentration is 50 ppb averaged

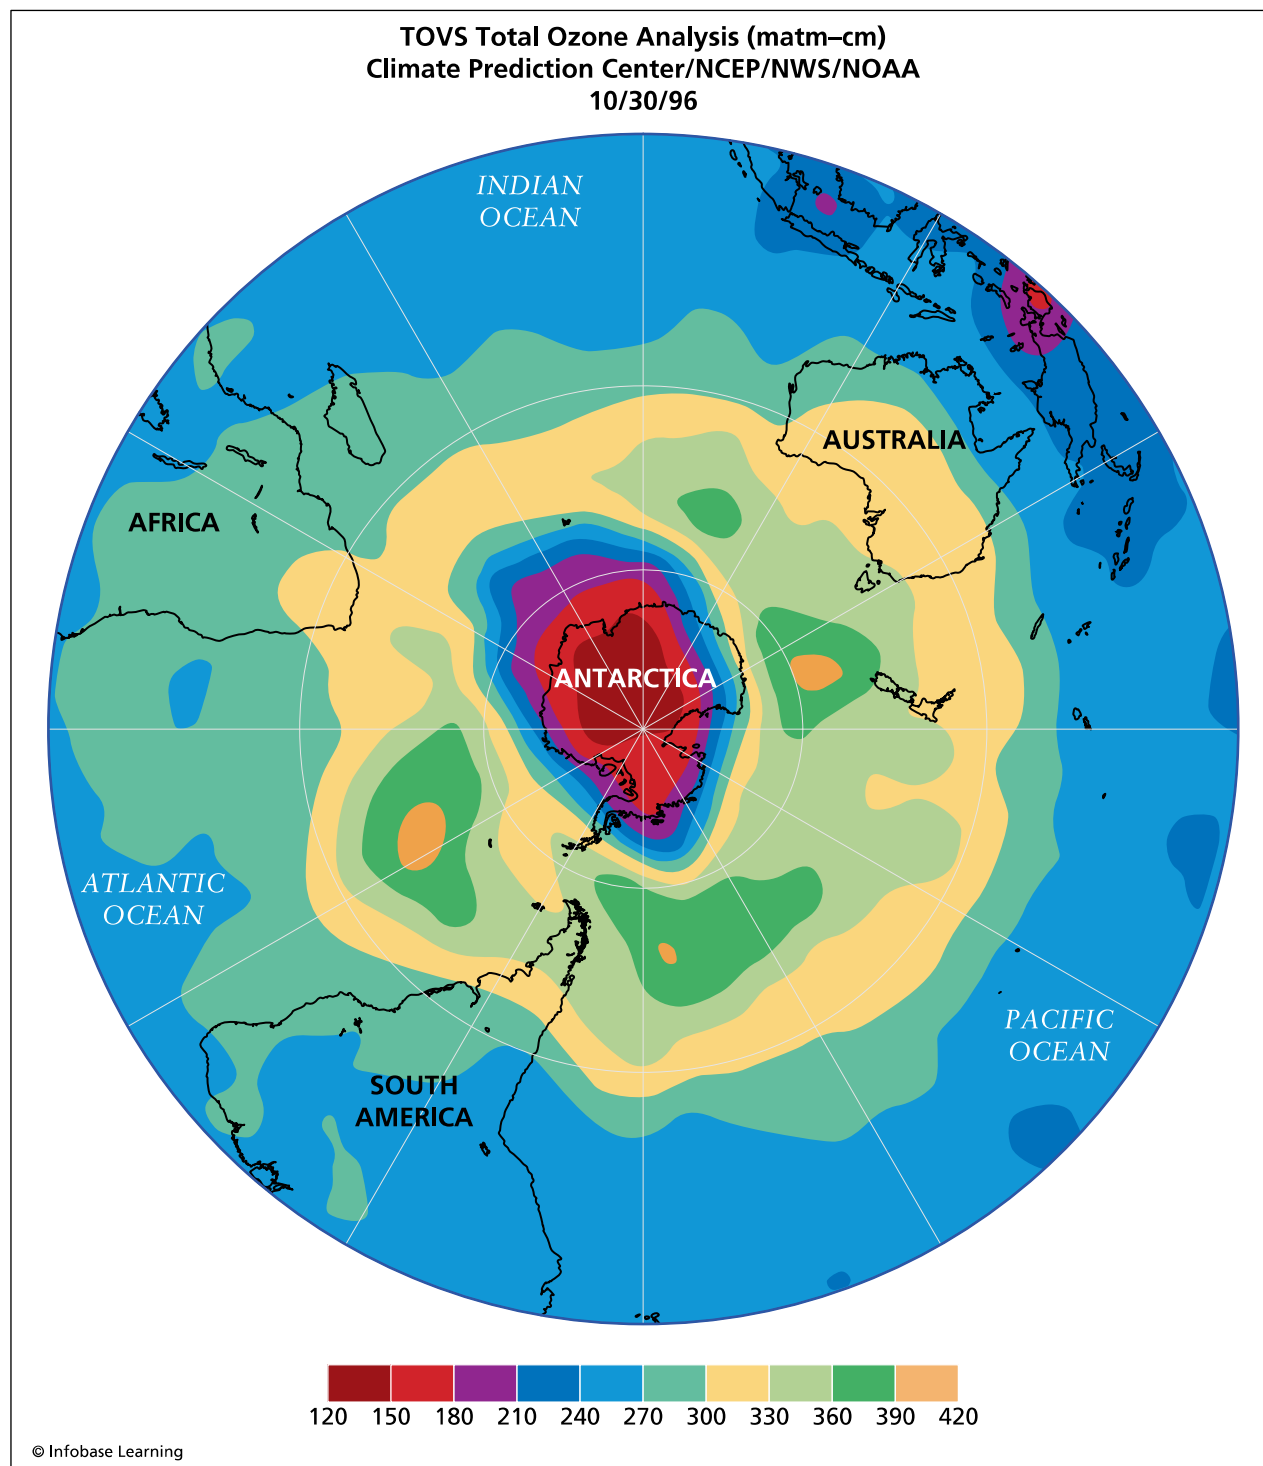

over eight hours. The good news is that the legislation appears to be working. On average, the ozone in American cities decreased from about 130 ppb in 1988 to 105 ppb in 1997. In contrast, ozone around cities in China is greatly increasing, with projected levels 25 percent higher than today's by 2050.

**ozone and chlorofluorocarbons** Ozone is elemental oxygen that has been changed from its most stable form, diatomic oxygen, or O<sub>2</sub>, to the much more reactive form, triatomic oxygen, or O<sub>3</sub>. It is formed naturally in the upper atmosphere, the lower part of the stratosphere, as ultraviolet light from the Sun energizes floating oxygen molecules. This causes some of the O<sub>2</sub> molecules to break apart

**South Polar projection of the Earth with the density distribution of stratospheric ozone superimposed on it. A large “hole” in the ozone layer appears over the Antarctic as the result of destruction by chlorofluorocarbons (CFCs).**

and then rejoin to form  $O_3$ . Ozone also can be formed when an electrical current discharges through the air, such as during a lightning storm. The energy released by the spark causes oxygen in the air to break apart, with a portion of it re-forming as ozone.

Physically, ozone is a pale blue gas with a sharp odor, often present in the air after a thunderstorm or near an old or failing electric motor. At  $-170^\circ\text{F}$  ( $-112^\circ\text{C}$ ), ozone condenses to a dark blue liquid, and it freezes at  $-315^\circ\text{F}$  ( $-193^\circ\text{C}$ ). The main char-

acteristic that makes ozone a very useful material and a significant air pollutant is its reactivity. Ozone is a powerful oxidizing agent, much more so than  $O_2$ . It can break apart many different types of organic compounds and is used as bleach for waxes, oils, and textiles. It also is a strong deodorizing agent and effective germicide, used to sterilize air and drinking water. Commercial manufacture of ozone is done by passing an electrical current through  $O_2$  or dry air; the end product of ozone and  $O_2$  or ozone and air is suitable for most industrial applications.

The ozone that forms by natural atmospheric process is also not very stable. The energy present in the ultraviolet rays that initially broke apart the  $O_2$  and allowed the ozone to form also strikes the larger  $O_3$  molecule, splitting it up once again into single oxygen atoms and double oxygen molecules. Ozone also is destroyed through its chemical interaction with nitric oxide (NO), which is naturally present in the atmosphere. NO forms when nitrous oxide ( $N_2O$ ), a relatively inert gas, floats up through the troposphere and enters the stratosphere. Once  $N_2O$  is in the stratosphere, it reacts with oxygen atoms that are excited by ultraviolet rays to form nitric oxide. The nitric oxide then combines with ozone to form nitrous oxide and oxygen:

As Earth's atmosphere evolved, the processes that created and destroyed ozone eventually reached equilibrium. If the amount of ultraviolet radiation from the Sun increased, the concentration of ozone in the stratosphere also increased. As ultraviolet activity weakened, ozone concentrations began to drop. The final outcome of this balance was the formation, within the Earth's atmosphere, of a comparatively thin zone, or band, more popularly known as the ozone layer, where ozone is formed and destroyed. It is about 13 miles (21 km) thick, but even within this band, ozone is rare. For every 10 million molecules of air in the lower stratosphere, there are only three ozone molecules. If all the ozone in this 13-mile- (21-km-) wide band were compressed, it would form a layer about as thick as a dime.

As sparse as it is, ozone plays a vital role in shielding the Earth's surface from the Sun's dangerous ultraviolet radiation. Its presence is as vital to our long-term health and quality of life as reliable sources of clean water. Ozone level is a global issue, threatening our very survival on the planet, when not enough ozone is present in the stratosphere.

The creation of ozone acts as an effective filter or barrier for the ultraviolet radiation that is constantly

bombarding the Earth from the Sun. This ultraviolet radiation is very energetic and, if left unchecked, can damage or destroy most tissue of plants and animals. Normal diatomic oxygen filters most high-level ultraviolet radiation, that with wavelengths shorter than 240 nm. It is the absorption of this radiation that causes it to break, or change  $O_2$  molecules into single oxygen atoms (O). There is a large amount of ultraviolet radiation with wavelengths between 240 nm and 290 nm that  $O_2$  cannot absorb. It is this longer-wavelength ultraviolet radiation that is absorbed by the ozone layer, providing the energy for the temporary joining of  $O_2$  molecules and O atoms into  $O_3$ .

### DEVELOPMENT OF CFCs

Refrigerators and refrigeration systems were introduced in the late 1800s and by the 1920s were common household appliances. Early refrigerators were kept in the yard or back porch because, until 1929, the coolant was a toxic gas, usually ammonia ( $NH_3$ ), methyl chloride ( $CH_3Cl$ ), or sulfur dioxide ( $SO_2$ ). It was not uncommon, in the early 1920s, for entire families to be asphyxiated by a coolant leak from their refrigerator. In response, the three principal makers of refrigerators at the time—Frigidaire, General Motors, and DuPont—joined to develop a less dangerous method of refrigeration. By 1928, they had an answer. A chemist with General Motors, Thomas Midgley, Jr., developed a “miracle compound” and named it Freon.

Quickly patented by DuPont, Freon was the first of a class of chemicals called chlorofluorocarbons, or CFCs. They are aliphatic organic compounds containing carbon and fluorine and, in other formulations, halogens and hydrogen. Colorless, odorless, nonflammable, nontoxic, and noncorrosive, CFCs are chemically nonreactive and very stable. Their best feature is that their boiling point is close to room temperature (77°F [25°C]), and they can be transformed readily from a gaseous to a liquid state, making them excellent coolants for refrigerators and air conditioners. In refrigerators, as liquids evaporate, they absorb heat, a process known as latent heat transfer. Freon and other CFCs evaporate at very low temperatures, and, as such, these substances can create cooling or freezing conditions very readily. Freon 14's boiling point is 78.8°F (23.8°C). They also have been used in fire extinguishers and as aerosol propellants, solvents, and foaming agents.

Freon is nontoxic and, therefore, eliminated the danger posed by refrigerator leaks. In just a few years, compressor refrigerators using Freon became

**Graph showing total emissions of CFC-11 and CFC-12 (solid lines), two of the most common CFCs, versus years from 1960 to 2000. There was a sharp decline in CFC emissions through the 1990s as the result of legislative actions on a global scale. Unfortunately, CFC concentrations in the atmosphere (dashed lines) continued to increase through this time as a result of previous releases. It will be several years before the concentration begins to decrease substantially. (Source: data from the U.S. Council on Environmental Quality)**

the standard for almost all home kitchens. In 1930, Thomas Midgley held a demonstration of the physical properties of Freon for the American Chemical Society by inhaling a lung-full of the new wonder gas and breathing it out onto a candle flame, which was extinguished, thus showing the gas's nontoxicity and nonflammability.

These miracle compounds are inexpensive to manufacture, long lasting, and inert. They were responsible for much of the modern conveniences of the 20th century and were used in numerous applications by almost every American on a daily basis. Every aerosol can used some form of CFC, as did every refrigerator and air conditioner. The cooling ability resulted in population shifts in the United States to southern areas that previously were underdeveloped because of their hot climate. As a result, CFCs became one of the highest-volume manufactured chemical groups in the United States.

### DAMAGE TO THE OZONE LAYER

It was only a few decades after CFCs were developed that scientists began to discover that they endangered the ozone layer and, with it, life on the entire planet. The reason that they are damaging to ozone is a result of the chlorine in the atom. Unattached chlorine atoms (Cl) break down ozone (O<sub>3</sub>) by the following reaction:

The chlorine is then regenerated when the ClO interacts with free oxygen atoms:

This cycle can continue for up to two years, the typical atmospheric lifetime for a chlorine atom, and during this time an average of 100,000 ozone molecules can be broken apart by a single chlorine atom. Eventually, the chlorine is removed from the atmosphere after it forms either hydrogen chloride or chlorine nitrate. These compounds tend to sink to the troposphere, where they are washed out by rain or other forms of precipitation.

Most forms of chlorine from bleach, swimming pools, industrial plants, seawater evaporation, and volcanoes do not reach the stratosphere. Chlorine from these sources combines with water vapor and is washed out of the troposphere. Only large fires and certain types of marine life can produce a stable form of chlorine that may reach the stratosphere. It is CFCs that make up approximately 85 percent of the chlorine in the stratosphere, and natural sources add the remaining 15 percent.

When those very stable and long-lived CFCs are released, they are able to reach altitudes well into the stratosphere, 15–25 miles (24–40 km) above the Earth's surface, without breaking down. There they undergo chemical reactions through exposure to ultraviolet radiation, which dissociates them, producing free chlorine atoms:

The free chlorine then participates in the ozone-consuming reactions described earlier. The behavior of chlorine in the atmosphere and its potential catastrophic effect on the ozone layer were first explained in 1974 by Mario Molina and F. Sherwood Rowland working at the University of California. They realized that CFCs could gradually make their way into the ozone layer and be broken down by ultraviolet radiation. Once liberated, the chlorine would begin to interact with and destroy ozone molecules. They presented a series of calculations demonstrating that if CFCs were to continue to be released at the current (1974) rate, the ozone layer would be significantly depleted in a few decades.

CFCs were valuable and useful industrial chemicals utilized around the world, and Molina and Rowland's prediction of a thinned ozone layer and worldwide adverse health effects caused a scientific sensation. Some researchers and climatologists attacked their methodologies, instrumentation, and calculations, whereas others began their own

## COMMONLY USED CFCs

Trade Name	Chemical Name	Usage
CFC-11 (Freon 11)	Trichlorofluoromethane ( $\text{CCl}_3\text{F}$ )	Used primarily as a propellant in aerosol sprays. Banned in the United States in 1978. Also used as a refrigerant, foaming agent for polyurethane foams, solvent and degreaser, and fire-extinguishing agent.
CFC-12 (Freon 12)	Dichlorodifluoromethane ( $\text{CCl}_2\text{F}_2$ )	Applications included use as a leak-detecting agent and in direct-contact food freezing. Widely used in restaurants and bars to chill or frost cocktail glasses and beer mugs. Many biological laboratories used this CFC to prepare frozen tissue sections. Used in manufacture of aerosols for cosmetics, pharmaceuticals, insecticides, paints, adhesives, and cleaners. Formerly, the main component of many home and commercial air-conditioning and refrigeration systems.
CFC-113 (Freon 113)	1,1,1-trichlorotrifluoroethane ( $\text{C}_2\text{F}_3\text{Cl}_3$ )	Chemical used in the manufacture of fluoropolymers. Also used in fire extinguishers and in the drying and degreasing of electronic parts and equipment. It is also commonly applied as a dry-cleaning solvent for all fabrics, leather, and suede. Also serves as a refrigerant in commercial or industrial air-conditioning and industrial process cooling systems.
CFC-114 (Freon 114)	Dichlorotetrafluoroethane ( $\text{C}_2\text{F}_4\text{Cl}_2$ )	Temperature-sensing agent, refrigerant, foaming agent, and aerosol propellant.
CFC-115 (Freon 114)	Chloropentafluoroethane ( $\text{C}_2\text{F}_5\text{Cl}$ )	Refrigerant and aerosol propellant.

experimental programs to try to confirm or repudiate Molina and Rowland's findings. Within a few years, there was widespread acceptance within the scientific community that Molina and Rowland were correct; several studies even found that they had underestimated the risk.

Even with the dire predictions, it took another 10 years and another startling scientific finding before the political systems finally recognized the danger. In 1985, scientists with the British Antarctic Survey, Joseph Farman, Brian Gardiner, and Jonathan Shanklin, published a paper describing an "ozone hole," or depletion in the stratosphere, over the Antarctic. The highest rates of depletion occur mainly over Antarctica and, to a lesser extent, the North Pole. These results formed the basis of a massive publicity and educational campaign by scientists and environmentalists aimed at policy makers and the public. The efforts led directly to the prohibition on the use and release of CFCs and other types of ozone-depleting chemicals.

For their pioneering work on upper atmosphere ozone chemistry, Molina and Rowland shared the 1995 Nobel Prize in chemistry with Paul Crutzen,

one of the world's leading researchers in mapping the chemical mechanisms that measure stratospheric ozone concentration.

## THE POLICY ON OZONE

In 1987, the United Nations brokered an international treaty called the Montreal Protocol that required most developed countries to stop using CFCs and banned all uses of the gases most dangerous to ozone by 1996. It will take time for the Montreal Protocol to have any real effect. Ozone-depleting gases are still making their way into the stratosphere, and it is likely that the ozone layer will continue to be stressed, as most models do not predict a turnaround until the early 2000s. It will be almost 100 years after that when the ozone layer will reach pre-CFC levels.

HCFCs (hydrochlorofluorocarbons) and HFCs (hydrofluorocarbons) are the chemicals being used to replace CFCs. They have less chlorine and are, therefore, less prone to react with stratospheric ozone. HCFCs and HFCs are ozone-depleting gases, but they are much less destructive than CFCs. The Montreal

Protocol requires that they, too, must be phased out by 2030. A more ozone-compatible replacement for these chemicals will have to be developed in the near future.

### HEALTH CONSEQUENCES

With a thinning ozone layer there is increased exposure to ultraviolet radiation (UVR). The most severe effect of that increased exposure is an upsurge in the rate of skin cancer. When UVR damages the deoxyribonucleic acid (DNA) in skin cells beyond the body's ability to repair them, the damaged cells begin to grow and multiply at an uncontrollable rate and a tumor (skin cancer) develops. Skin cancer generally, first, appears in the outermost layer of skin, the epidermis, allowing early detection of most skin cancers. The disease can be divided into two basic types, nonmelanoma skin cancer, which includes basal cell cancer and squamous cell cancer, and melanoma, as shown in the table.

Nonmelanoma skin cancers develop slowly and have very effective treatment regimens. They rarely

are fatal, although squamous cell cancers result in an estimated 2,200 deaths every year in the United States. At least 1 million cases of basal cell and squamous cell skin cancers are reported annually in the United States, more than double the number of diagnosed cases from 20 years ago. If not treated promptly, nonmelanoma skin cancers spread and become disfiguringly large. Although less common, malignant melanoma is far more dangerous. It accounts for about only 5 percent of the total number of skin cancer cases reported in the United States but causes 75 percent of skin cancer-related deaths. Some 54,000 new cases of melanoma are diagnosed each year, and about 7,800 people lose their lives to it despite improvements in diagnosis and treatment.

Higher levels of UVR also have other human health effects, including increased susceptibility to sunburn and premature aging of the skin. Other potential effects of increasing UVR concentrations, which are still being studied, may consist of eye damage such as inflammation of the cornea, forma-

### TYPES OF SKIN CANCER AND TREATMENT

Type	Description	Treatment
Basal cell carcinoma (also called epithelioma or basal cell cancer)	Forms in the basal cell layer, the innermost layer of the epidermis. Most common form of skin cancer. Many different appearances: red patch or irritated area; smooth, shiny, and waxy-looking bump; a white or yellow scarlike area; smooth reddish growth. Chronic exposure to sunlight is the cause of almost all basal cell carcinomas.	Basal cell carcinoma grows slowly and does not usually spread to other parts of the body (metastasize). Most common treatment is curettage and electrodesiccation—scraping away the tumor and then destroying a thin surrounding layer with heat. Other treatments include surgical excision and cryosurgery (freezing with liquid nitrogen).
Squamous (scaly) cell carcinoma	Develops in the cells of the epidermis that make keratin. Occurs most commonly on Sun-exposed parts of the body and develops over a long period. Mucus membranes, especially the lip, can also be affected.	Surgical removal is the most effective way to control this type of skin cancer. Lasers, cryotherapy (freezing), and topical medications can be helpful in very early, superficial stages. Radiation treatments are used for more advanced cases. When properly treated, the cure rate is high. Squamous cell carcinoma can grow quickly and, unlike basal cell, spread to other parts of the body.
Melanoma	Arises in the pigment-producing cells (melanocytes) of the skin. Appears as a new mole or on an existing mole or discoloration of the skin. It has the potential to spread to other sites or organs in the body. Accounts for only about 4 percent of all skin cancer cases; causes the majority of skin cancer-related deaths. The main cause is overexposure to ultraviolet radiation (sunlight).	Removal of the tumor is the treatment of choice for early-stage melanoma. In later stages of the disease, surgery is generally followed with chemotherapy, radiation, or immunotherapy. The chance of developing melanoma increases with age. It is one of the most common cancers in young adults and those who tend to sunburn easily. People who work outdoors or live in areas where sunlight is very strong (the American Southwest) are at higher risk.

tion of corneal lesions, and cataracts. Some evidence also points to UVR as an immune system suppressant.

## **Pacific Gas & Electric Company Hinkley, California (1987–1997) Water Pollution**

Few environmental disasters are widely known by the public. Several of the major oil spills were recognized for a while after they occurred, such as the Santa Barbara oil spill in California the *Exxon Valdez* spill in Alaska, and nuclear disasters such as those at Chernobyl and Three Mile Island. These, however, were very important events with far-reaching consequences. Most less dramatic pollution episodes and sites, such as the more than 1,800 Superfund sites in the United States, are unnoticed by everyone except the local residents affected and regulatory agencies. An exception to this is the Woburn, Massachusetts, well G and H site, because it was made into a movie in 1998 titled *A Civil Action*. The Pacific Gas & Electric Company site in Hinkley, California, is even better known, as it was the subject of the 2000 film *Erin Brockovich*—the most commercially successful film about an environmental problem, with its leading actress, Julia Roberts, winning an Academy Award as “Best Actress” for her portrayal of the title role. This popularized event was the chromium contamination of a small town in California.

### **BACKGROUND**

Chromium is a dense, malleable metal that is steel gray in color. One of the main properties of chromium is that it can be polished to a high brilliance. Chromium also resists corrosion and has been added to steel and other metals to improve both their appearance and their performance under extreme conditions. Some of its first uses were in dyes and paints. Chromium is also a widely used dietary

supplement. It is an essential trace metal required for healthy mammalian metabolism. In its trivalent form, chromium, as does insulin, reduces blood glucose levels and can be used to control certain types of diabetes. In proper doses, chromium helps to lower low-density lipoprotein (LDL) cholesterol levels.

Chromium also has special electrochemical characteristics including three valence states: +2 (divalent), +3 (trivalent), and +6 (hexavalent). Trivalent chromium (+3) occurs naturally in the environment, and compounds of it are used for plating, in the formulation of dyes and pigments, in leather tanning and finishing, and in wood preserving. Trivalent chromium also is the form that is needed for the proper functioning of human and many other animal metabolisms. Hexavalent (+6) chromium is artificially manufactured and is used in combination with sulfuric acid and water in industrial metal plating baths and in leather tanning operations. Hexavalent chromium also can form during heating of other forms of the compound. Hexavalent chromium acts aggressively inside the human body. Breathing high levels can irritate or damage the nose, throat, and lungs. Irritation or damage to the eyes and skin also can occur if it contacts these organs in high concentrations or for a prolonged period. Repeated or prolonged exposure can damage the mucus membranes of the nasal passages and result in ulcers. In severe cases, exposure causes perforation of the septum, but this effect appears dose-related, and breathing small amounts of hexavalent chromium, even for long periods, usually does not cause respiratory tract irritation in most people. Some individuals become allergic to hexavalent chromium, so that inhaling the chromate compounds can cause asthma.

All forms of hexavalent chromium (dissolved in liquids, respirable dust, vapors, fumes, mists, etc.) are regarded as carcinogenic. The risk of developing lung cancer increases with the amount of hexavalent chromium inhaled and the duration of exposure. Studies of workers in chromate production, chromate pigment, and chrome electroplating industries employed before the 1980s, when current safety standards went into effect, show increased rates of lung cancer mortality. Certain hexavalent chromium compounds produced lung cancer in animals that had the compounds placed directly in their lungs.

### **POLLUTION OF THE SITE**

One of the more well-known examples of potential chromium exposure occurred in the small town of Hinkley, California (a population of about 1,900 as of this writing), located in the Mojave Desert, approximately 120 miles (192 km) northeast of Los Angeles. As part of its natural gas distribution system, in 1952, the Pacific Gas & Electric (PG&E) Company constructed and operated a gas pipeline that extended from Texas through most of California. Founded in 1905, PG&E is one of the oldest and largest public utilities in the United States, supplying gas and electricity to most of northern California. Associated with this natural gas pipeline were a series of large complex compressor stations. At about every 300 miles (500 km), the pressure in the natural gas pipeline needed to be increased to ensure its continued uninterrupted flow to commercial and residential customers. One of these compressor stations is just outside Hinkley. During repressurization of the gas, large amounts of heat are generated, and to dissipate this heat, PG&E ran water around and through the compressors. The hot water was then fed into a series of cooling towers and recycled through the compressors.

As part of the compressor station's routine equipment maintenance procedures, a rust inhibitor was added to the cooling water. This rust inhibitor contained hexavalent chromium as one of its main active ingredients. Over time, the cooling water became contaminated with small particles of grit and metal called undissolved or settleable solids. When concentrations of these solids reached a certain level, PG&E discharged the water into a series of unlined pits or settling basins. This practice went on until 1972, when changes mandated by the new California Regional Water Quality Control Board (RWQCB) regulations took effect and required that the settling basins be lined with an impervious material, such as clay or plastic. Lining the ponds reduced the likelihood that contaminants present in the cool-

ing water would infiltrate the soil from the ponds and enter the groundwater.

By then, it was already too late. PG&E had discharged an estimated tens of thousands of gallons of hexavalent chromium-contaminated water into the unlined ponds. This resulted in the contamination of the groundwater that the residents of Hinkley used for drinking, bathing, cooking, and filling their swimming pools. PG&E also used a spray aeration technique (jetting the water into the air) as a way to dispose of contaminated water. As this water evaporated, the settleable solids that had been floating in it became airborne as dust and particulate.

In 1987, PG&E notified the RWQCB that it had detected hexavalent chromium in several nearby groundwater wells. The reported concentrations were in the 0.6 part per million (ppm) range, above the federal MCL of 0.1 ppm, as well as the California standard of 0.05 ppm. As the investigation into the extent of contamination proceeded, PG&E, as did many corporations at the time, kept the findings of its environmental investigations secret and did not alert the residents of Hinkley that its public water supply contained hexavalent chromium. PG&E admitted years later that this was a mistake and that they should have promptly informed those people drinking the water of the presence of hexavalent chromium. Concerned over potential impacts to their health and property values, in the early 1990s, 648 residents of Hinkley joined in a class action suit against PG&E, spearheaded by the law firm of Masry & Vitoe, in combination with two other, much larger law firms, as well as Masry & Vitoe's flamboyant legal assistant, Erin Brockovich.

### **LAWSUIT AGAINST PG&E**

The basis of the class action lawsuit was that chronic (long-term) exposure to low levels of hexavalent chromium had resulted in a wide variety of illnesses and disabilities including uterine cancer, breast cancer, Hodgkin's disease, cancer of the brainstem, gastrointestinal cancer, miscarriages, nosebleeds, asthma, heart failure, damaged immune systems, and many other types of health problems. PG&E agreed to settle the case via private binding arbitration and not through a traditional public trial. During the arbitration process, medical and scientific experts for both sides presented evidence affirming and refuting the basis for the plaintiffs' health claims. Ms. Brockovich also procured a laboratory report that indicated that hexavalent chromium levels in one water supply well were in the 20-ppm

range, not the 0.6-ppm concentration claimed by PG&E. In 1997, PG&E settled the claims for \$333 million, one of the largest toxic tort judgments ever awarded in the United States.

The lawyers representing the plaintiffs took as their fee \$133 million. Ms. Brockovich received a \$2 million bonus. After \$10 million in expenses, the remaining \$188 million (about \$300,000 per individual) was distributed by the attorneys to the plaintiffs, on the basis of the severity of their illnesses. As part of the settlement, PG&E admitted no guilt or fault for damaging anyone's health, but they did agree to take full responsibility for the cleanup of the groundwater. PG&E passed along the costs of the Hinkley settlement to its customers but declared bankruptcy in 2001 in an electrical rate-fixing scandal that also contributed to the recall of the then California governor Gray Davis. Arnold Schwarzenegger was elected governor of California in his place. After a state-sponsored bailout of its finances, PG&E emerged from bankruptcy in 2004 under new management and continues to provide electricity and natural gas to the citizens of California, albeit at some of the highest rates in the country.

**PAH (polycyclic aromatic hydrocarbon)** Even though there is very little industrial production of PAH compounds, they are among the most widespread of the organic pollutants. They are primarily produced through incomplete burning of carbon-based compounds but also present in several common products. There are about 100 PAH compounds, and about 15–20 (depending upon the source) are considered to be significant health hazards. They include many of the following:

acenaphthene  
 acenaphthylene  
 benz(a)anthracene  
 benzo(a)pyrene  
 benzo(b)fluoranthrene  
 benzo(e)pyrene  
 benzo(k)fluoranthrene  
 benzo(j)fluoranthrene  
 dibenz(a,h)acridine  
 dibenz(a,h)anthracene, or anthracene  
 dibenz(a,j)acridine  
 dibenzo(a,e)pyrene  
 dibenzo(a,h)pyrene  
 dibenzo(a,i)pyrene  
 dibenzo(a,l)pyrene (pyrenes)  
 7H-dibenzo(c,g)carbazole  
 fluorene  
 indeno(1,2,3-cd)pyrene  
 5-methylchrysene, or chrysene  
 phenanthrene

They are also more commonly found in Superfund sites, and there is a greater likelihood of human exposure.

In the first 1,408 hazardous waste sites that the U.S. Environmental Protection Agency (EPA) assigned to the National Priorities List (Superfund sites), 600 were found to contain PAHs, although not all may have been evaluated for them. As a result of the widespread distribution and adverse health effects caused by exposure to PAHs, they were ranked the eighth most dangerous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

#### PROPERTIES AND USES

Pure PAH compounds are colorless, white, or yellow-green crystalline solids. Some are used in medicines, dyes, plastics, and pesticides, and others are used only in laboratory biochemical or biomedical research. Most PAHs are found in mixtures of other substances. At least eight of those listed are found in coal tar, which has a variety of applications from

treatment of skin ailments such as eczema and psoriasis in shampoo and ointments to fuel for steel industry furnaces. It is also used to make coal tar pitch and creosote. At least six of the listed PAH compounds are contained in coal tar pitch, which is used for aluminum production, roofing, and surface coatings, among other uses. At least two of the list are constituents in creosote, which is a common preservative for railroad ties, telephone poles, and pilings in marine areas and is sometimes used as fuel for steel production. At least three of the list are constituents in bitumens and asphalt, whose primary use is in paving but also in making objects soundproof and waterproof and in pipe coatings. Suppliers for the PAHs listed are few in number, ranging from two to 20.

### ENVIRONMENTAL EXPOSURE AND FATE

PAH is produced by incomplete burning of organic compounds. In general, PAHs occur in exhaust from gasoline and diesel engines, smoke from open burning, industrial smoke emissions, coal tar and pitch, coke oven emissions, asphalt, creosote, mineral oil, soot, tobacco and its smoke, and charcoal broiled foods. Benzo(a)anthracene is found in exhaust fumes, tobacco smoke, general soot and smoke, coal tar and pitch, amino acid, fatty acid, waxes, solvents, mineral oil, and creosote. Benzo(b)fluoranthene is also in exhaust, tobacco and its smoke, tar, soot, and amino and fatty acid pyrolysis. Benzo(j)fluoranthene is in exhaust, tobacco smoke, crude and used motor oil, and coal tar. Benzo(k)fluoranthene is in the same products as benzo(j)fluoranthene plus lubricating oil. Benzo(a)pyrene is in all of the general PAH sources and pyrolysis products of carbohydrates, amino acids, fatty acids, shale oil, and commercial solvents. Dibenz(a,h)acridine is in tobacco smoke condensate, coal smoke and soot, petroleum refineries, and incinerators. Dibenz(a,j)acridine has the same sources as dibenz(a,h)acridine. Dibenz(a,h)anthracene is in car exhaust, cigarette smoke, soot, and coal tar. The compound 7-H-dibenzo(c,g)carbazole is in cigarette tar. Dibenz(a,e)pyrene is in exhaust, fossil fuel, and tobacco smoke. Dibenz(a,h)pyrene is in exhaust, coal tar, and tobacco smoke, as are dibenzo(a,i)pyrene and chrysene, and dibenzo(a,l)pyrene is also in coal gasification products. Indeno(123-cd)pyrene is in exhaust, tobacco smoke, benzene and pyrene pyrolysis products, coal tar and pitch, and asphalt. The PAHs vary in amount of emissions to the environment. Some 1.8 million pounds (818,181 kg) of benzo(a)pyrene is emitted from stationary combustion sources, but 96 percent of it is from the weathering, processing, and burning of coal.

PAHs have various fates in the natural environment. They are mainly released to the air from forest fires, residential heating and burning, automobile and truck exhaust, and volcanoes. They enter surface water from industrial wastewater discharge, from wastewater treatment plants, and from air pollution fallout and washout from precipitation. They can be released to soil from industrial spills, dumping, leaks from hazardous waste sites, mining spoils, and air pollution fallout. In air, PAHs are typically vapors and adhere to particulate matter, where they can travel long distances before settling to the ground. The vapors are subject to photochemical breakdown and reactions with other atmospheric chemicals. In surface water, they also tend to bind tightly to particles and sediments and settle to the bottom or evaporate at the surface. They tend not to undergo significant biodegradation. A significant amount of the PAHs will also evaporate from the surface of soil. The rest will bind tightly to soil particles and largely remain fixed, with only small amounts leaching into the groundwater system. The dominant degradation process in soils appears to be the result of microbial activity. In aquatic and marine systems, PAHs tend to bioaccumulate significantly, especially in zooplankton and filter feeders.

### TOXICOLOGY AND HEALTH EFFECTS

Human consumption of PAHs is largely through smoking and consuming contaminated foods such as grilled meat and fish, as well as from air and water from contaminated areas. Acute exposure to PAHs can result in red blood cell damage and consequent anemia and immune system damage. Long-term chronic effects include reproductive problems and developmental problems. The real danger of PAHs, however, is that those described here are documented animal carcinogens and reasonably anticipated to be human carcinogens. Benzo(a)anthracene has produced cancer of the stomach, lungs, heart, kidneys, skin, and bladder and at injection sites in mice. Benzo(j)fluoranthene has produced skin and injection-site cancer in mice and pulmonary squamous cell carcinomas in rats. Benzo(a)pyrene has been shown to cause cancer of the skin in mice, rats, guinea pigs, hamsters, rabbits, newts, and subhuman primates and cancer of the lungs at injection sites. Cancer of the stomach, mammary glands, and brachial tubes were also commonly produced in mice, rats, and hamsters. Benzo(b)fluoranthene can induce skin tumors and local carcinomas. Dibenz(a,h)acridine and dibenz(a,j)acridine have been found to cause skin tumors and lung cancer in mice. Dibenz(a,h)anthracene has been shown to induce injection-

site sarcomas in rats, guinea pigs, pigeons, other fowl, and adult and newborn mice, including lung cancer from injection into lung tissues. Injection into the kidneys of frogs resulted in kidney cancer. Mice also experienced cancer of the forestomach, lungs, and mammary glands from general exposure. 7H-dibenzo(c,g)carbazole induced injection-site tumors in rats, respiratory tract tumors in hamsters from intratracheal injection, and forestomach tumors and hepatomas from general exposure in mice. Topical and injection exposure of dibenzo(a,e) pyrene, dibenzo(a,h) pyrene, dibenzo(a,i) pyrene, and 5-methylchrysene induced skin and injection-site sarcomas in mice.

Several studies suggest cancer in humans can result from exposure to PAHs. Exposures to coke oven emissions that contain mixed PAHs have been shown to cause increases in lung and urinary tract cancers in workers. Exposure to creosote that contains PAHs has been shown to cause skin tumors. Cigarettes, coal tar, coal tar pitch, and bitumens contain PAHs and are also associated with increased lung cancer, although there may be contributing factors. Skin contact with coal tar and shale oil, sources of PAHs, is associated with increased incidence in skin cancer.

### REGULATIONS ON HUMAN EXPOSURE

Several federal agencies have made recommendations and regulations regarding use, release, and exposure to PAHs. The EPA has provided suggested intake limits for PAHs for each 2.2 pounds (1 kg) of body weight, including 0.3 milligram of anthracene, 0.06 milligram of acenaphthene, 0.04 milligram of fluoranthene, and 0.03 milligram of pyrene. The only PAH that is regulated under the Safe Drinking Water Act is benzo(a)pyrene, at 0.0002 mg/L. The EPA further regulates the amount of environmental releases of PAH that must be reported to the National Response Center, including one pound (0.45 kg) for each of benzo(b)fluoranthene, benzo(a) pyrene, and dibenz(a,h)anthracene; 10 pounds (4.5 kg) for benz(a)anthracene; 100 pounds (45.5 kg) for each of acenaphthene, chrysene, fluoranthene, and indeno(1,2,3-c,d)pyrene; and 5,000 pounds (2,272 kg) for acenaphthylene, anthracene, benzo(k)fluoranthene, benzo(g,h,i)perylene, fluorene, phenanthrene, and pyrene. Coal tar exposure in the workplace is regulated by the Occupational Safety and Health Administration (OSHA), National Institute of Occupational Safety and Health (NIOSH), and American Conference of Governmental Industrial Hygienists (ACGIH). OSHA established a limit of 0.2 mg of workplace air over an eight-hour-work-

day, 40-hour workweek. NIOSH's recommended exposure limit, time-weighted average (REL-TWA) is 0.1 mg per cubic meter of workplace air over a 10-hour-day, 40-hour workweek for PAHs in coal tar products. ACGIH sets a similar limit of 0.2 mg per cubic meter of workplace air over an eight-hour-workday, 40-hour workweek. Mineral oil exposure is also regulated by OSHA with a permissible exposure limit (PEL) of 5 mg per cubic meter of workplace air over an eight-hour-workday, 40-hour workweek; NIOSH sets a recommended exposure limit, time-weighted average (REL-TWA) of 0.1 mg per cubic meter of workplace air over a 10-hour-day, 40-hour workweek and a short-term exposure limit (STEL) of 10 mg per cubic meter of workplace air.

**Parsons Chemical Grand Ledge, Michigan (1979–2018) Soil Pollution** In April 1945, a small agricultural chemical company named Parsons Chemical Works, Inc., opened on a 6.5-acre (2.6-ha) property in Grand Ledge, Michigan, about 100 miles (160 km) northwest of Detroit, just outside Lansing. Parsons was expert in the manufacturing of pesticides, herbicides, and solvents, as well as arsenic- and mercury-containing products. These compounds are used to control agricultural pests with the active ingredients dissolved in high-vapor-pressure solvents that quickly evaporate once applied to the crop or

soil, leaving the pesticide in place. The plant operated a successful, even at times thriving business for more than 30 years, until it closed in summer 1979.

### POLLUTION OF THE SITE

During site operations, Parsons flushed process residues, off-spec product, and wash water into floor drains inside its building. In modern agricultural chemical companies, these types of wastes, which can contain high concentrations of pesticides, mercury, arsenic, and chlorinated hydrocarbons, are captured by floor drains or in sumps that are connected either to the facility's own wastewater treatment system, a holding tank, or the municipal sewer system. At the Parsons facility, these floor drains were connected to a septic tank.

In the United States, almost a quarter of the population relies on septic systems to provide safe, effective treatment of household sanitary wastewater. In general, the waste pipe from a house or, in some cases, small office building, connects to a large 1,000 to 2,000-gallon (3,785–7,571-L) buried concrete basin that is divided into two chambers. As wastewater enters the first chamber of the basin, solids settle to the bottom, and greases and oils float to the top. Liquids then flow through portals in the wall separating the two chambers into the second chamber, where further settling and clarifying take place. Anaerobic bacteria in the basin organically degrade the solids and help to clarify the liquids.

Eventually, clarified liquids are discharged to a series of lateral pipes buried several feet below the surface. These pipes, often made of ceramic tiles and called a tile field, or leach field, are designed to release slowly or leak the liquids into underlying soil. Once released into the soil, the remaining organic impurities in the liquids are further degraded by bacteria in the soil or are taken up by plants. The size of the leach field is dependent on the volume of wastewater that it must receive, and higher flows require larger fields.

A less typical problem related to septic systems results from the introduction of organic chemicals such as paints, bleaches, dyes, or pesticides that destroy the essential anaerobic bacteria present in the tank and leach fields that are the mainstay of this sanitary wastewater treatment process. Without the bacterial degradation that takes place both in the septic tank and in the soil underneath the leach field, wastewater may just as well be poured directly onto the ground.

The Parsons septic system received pesticides, solvents, and heavy metal residues that probably rendered the inside of the tank bacteria-free. Once

liquid residues moved out of the tank, they entered a drain field, which, in turn, was connected to a catch basin in Eaton County's storm-water drainage system. During periods of high-volume flows, liquid wastes not discharged into soil underlying the leach field moved through the catch basin, which emptied to an unnamed tributary northwest of the plant that eventually connected to Grand River. At some point during the operational life of the facility, soil covering the drainage pipes (tile field) eroded away, and liquid wastes simply ran down the bank of the unnamed stream, contaminating the underlying soil and directly entering the surface water system.

Parsons also dumped pesticide and solvent residues onto the soil surrounding the southern side of its building. Eventually, an entire acre became contaminated. Groundwater is present within 10 feet (3.1 m) of the surface at the Parsons property, and soils are very permeable, allowing ready migration of contaminants into the underlying water-bearing zone. The area surrounding the Parsons site is a mix of commercial and residential uses. The city of Grand Ledge (population 11,000) provides potable water to its citizens from municipal supply wells about three miles (4.8 km) from the site, and a number of small businesses and private homes in the vicinity of the Parsons plant rely on individual wells to meet their water supply needs.

As the nationwide hazardous waste regulations of the mid-1970s began to take hold, the operators of the Parsons facility must have realized what was in store for them because in 1979 they sold the business to ETM Enterprises, Inc. (ETM), a fiberglass manufacturer. Concerns over environmental quality at the site led to a request by the Michigan Department of Environmental Quality (MDEQ) that ETM perform some soil and groundwater sampling. It was during this investigation that the connection between the septic system and storm-water catch basin was discovered, and ETM and MDEQ began to realize quickly that a serious environmental problem was probably present on the property.

MDEQ, the Eaton County Health Department, the U.S. Environmental Protection Agency (EPA), and ETM all began a series of investigations designed to identify the magnitude and extent of the soil and groundwater contamination thought to be present on the Parsons site. By the mid-1980s, these studies had found that surface and subsurface soils, sediments in the unnamed stream, as well as sediment in Grand River were contaminated with pesticides including dieldrin, chlordane, dichlorodiphenyltrichloroethane (DDT) and its breakdown products, organic compounds, and inorganic compounds including mercury, arsenic, and chromium.

### THE CLEANUP

In 1984, the site was included in the National Dioxin Study. This was a two-year evaluation of approximately 1,000 pesticide manufacturing, formulation, and use facilities that was mandated by the U.S. Congress. Its objective was to determine the extent of dioxin in soil, water, and the local ecology including fish and other wildlife and was motivated by high-profile contamination incidents at Times Beach and Love Canal. Data from sampling on the Parsons property indicated that dioxins were present in sediments of the unnamed tributary on plant property and in soil from an approximately 140-square-foot (13.01-m<sup>2</sup>) area underlying the former septic system leach field.

Acting under pressure from MDEQ, ETM removed the septic tank and leach field and properly disposed of the contaminated sludge and liquid that were present inside the tank. ETM, which did not use, store, or handle pesticides and solvents, connected its own process and sanitary wastewater piping to the Grand Ledge municipal sewer system. Eventually MDEQ issued a letter releasing ETM from any further liability for site cleanup. With no responsible party available to fund needed soil and groundwater remediation, the Parsons site was placed on the National Priorities List as a Superfund site in 1989.

In 1990, MDEQ and USEPA initiated the first remedial action to clean up site soil. More than 3,000 cubic yards (2,294 m<sup>3</sup>) of contaminated soil was remediated by using an innovative technology called in situ vitrification, or ISV. The basic concept behind ISV is melting the contaminated soil into a pile of fused silica. The contaminant is left in place, entombed forever in an unleachable block of glass. The Department of Energy developed this technology for use on some of its more recalcitrant contaminants such as radionuclides, polychlorinated biphenyls (PCBs), heavy metals, and mixed hazardous and radioactive wastes.

To start the vitrification process, an electric current is applied to an array of electrodes that have been driven directly into the contaminant mass. The electrodes are connected to large generators or directly to the regional power grid, and, as electricity passes between electrodes, the soil is heated to very high temperatures of 2,900–3,600°F (1,600–2,000°C). Between the time when the water in the soil's pore spaces boils off at 212°F (100°C) and begins to melt at about 2,612°F (1,100°C), the soil becomes non-conductive. Without an electrical current, there is no heating, and the soil starts to cool. In order to keep the electricity flowing and the soil heating, a layer of conducting material, usually a mixture of graphite,

fused silica, and salt, is spread out on the surface. This starter path remains conductive even as the pore water is driven off. After the melting point of the soil is reached, it again becomes conductive.

The melting point of soil depends largely on the alkali metal oxide (sodium and potassium) content. The more alkali metal oxide present, the higher the melting point. As the soil melts, the molten zone grows outward and downward as the probes descend through the liquefying material. When the desired depth is reached, the electricity is shut off and the electrodes disconnected. The end result is a dense, chemically stable, leach-resistant glass. Blocks of glass weighing as much as 1,400 tons (1,274 metric tons) at depths greater than 20 feet (6.1 m) have been made by using this process. Most of the void spaces in the soil are removed during melting, and volume reductions of 20–50 percent have been reported at some sites. During melting, organic compounds are vaporized and collected in a hood or tent for treatment prior to release into the atmosphere.

At the Parsons site, MDEQ and USEPA directed that the soil targeted for ISV treatment be excavated and placed, or staged, in a series of two concrete wall trenches 15 feet (4.6 m) deep and 27 feet (8.2 m) wide. One trench was 168 feet (51.2 m) long and the other 84 feet (25.6 m) long. Contaminated debris such as concrete, steel, used filters, and automobile tires was also included in these trenches. A two-foot (0.6-m) layer of uncontaminated soil was placed across the top of each trench. The trenches were divided into nine cells, each 27 feet long (8.2 m), by 27 feet (8.2 m) wide, by 15 feet (4.6 m) deep.

Vitrification of the contaminated soil at the Parsons site was scheduled to be completed in about three months but took almost a year. The reasons for this delay ranged from very stringent oversight by regulators that required permit modifications for almost every change in procedure to operational learning-curve issues on how best to manage the infiltrating groundwater and at what rate to supply power to the electrodes. Despite the extended schedule, overall, the remediation was successful. As the operators became more familiar with the system, they found that they could overlap the melt areas and needed only eight melts to treat the soil in the nine cells. Additionally, through proper system management, they could form a "cold cap," or thin surficial layer, of vitrified soil over the melt area and help contain vapors and fumes being given off during the process.

To evaluate the effectiveness of ISV, soil samples were taken before and after melting. These data indicated that ISV was very effective not only in reducing total contaminant concentrations, but also

in immobilizing the remaining contaminant mass into a nonleachable form.

Subsequent remedial actions included the excavation and off-site disposal of another 1,200 cubic yards (917.5 cubic m<sup>3</sup>) of contaminated soil that was identified during ISV. This volume of material was too low to justify reuse of ISV economically. Also, approximately 3,800 cubic yards (2,905 m<sup>3</sup>) of arsenic-contaminated soil was removed from areas across the highway from Parsons, washed there by surface water runoff from the site.

To address contaminated groundwater, MDEQ and USEPA took a much less aggressive approach. Water samples from approximately 70 private supply wells within a quarter-mile (0.4-km) radius of the site had been tested periodically and found not to be affected by site-related constituents, although some contained elevated levels of naturally occurring manganese and zinc. Wells in the area draw water from a deep bedrock aquifer that had not been contaminated by pesticides or other chemicals originating at the Parsons site.

On the basis of these findings and the fact that on-site, contaminated soil had been addressed, MDEQ and USEPA decided to implement a long-term monitoring program that includes periodic sampling of selected residential drinking water wells until 2018. If monitoring data indicate that contamination is moving toward private water supply wells, contingency plans have been established to provide these residents alternate drinking water supplies until they can be connected to the Grand Ledge municipal water supply.

**particulate** In the 1970 Clean Air Act, particulate was designated as one of the six "criteria" air pollutants along with carbon monoxide, lead, nitrogen oxides, sulfur dioxide, and volatile organic compounds. At that point, it was not subdivided and considered to be among the more benign of the six. With continuing research since, particulate has emerged as one of the most dangerous of the six, been officially subdivided into different types, and been subject to much more stringent regulations, which are controversial in that many scientists think that they are not stringent enough. It has been estimated to be responsible for as many as 65,000 deaths per year in the United States from respiratory effects and as many as 200,000 deaths per year in Europe under the old restrictions. This constitutes a 17 percent increase in mortality risk. In recent years, new legislation has been rushed into enactment to deal with this crisis. Even with the new legislation, people who have respiratory or cardiac problems who live in almost any urban area of the United States and even many suburban and rural areas must be extra careful about exposure to particulate pollution.

## PROPERTIES AND SOURCES

*Particulate* is a general term for any solids or small liquid particles that are suspended in air. They can be composed of literally hundreds of elements and compounds, some of which may be hazardous including heavy metals and asbestos. Particulate falls into several categories based upon size. Total particulate matter (TPM) is all suspended matter within the size range of 100 and 0.1 micrometers. Within this grouping, the PM<sub>10</sub> classification, are particles less than 10 micrometers, and PM<sub>2.5</sub> are less than 2.5 micrometers. The main reason for the subcategories are medical: PM<sub>10</sub>, or coarse, particles are respirable; PM<sub>2.5</sub>, or fine, particles can be absorbed directly into the bloodstream through the lungs. Primary particles, also known as direct particles, are emitted directly from their source as solids and are primarily PM<sub>10</sub> or larger. Secondary, or indirect, particles are formed in the atmosphere primarily through photochemical reactions of precursor

**Chart showing the sizes of particulate pollution and some common items for comparison in log scale. The sizes represented by the shaded area cause the greatest damage to human lungs when inhaled.**

chemicals and primarily fall into the  $\text{PM}_{2.5}$  range. Sources of particulates are both natural and anthropogenic. Natural particulate is a combination of solids including dirt, soil and rock dust, sea salt, pollens, molds, fungi, yeast, bacteria and viruses, ashes and volcanic ash, and liquid droplets of aerosols from biologic activities and volcanoes. Anthropogenic sources include cars, trucks, buses, construction sites, agricultural fields, unpaved roads, stone crushing operations, brickworks, cement works, quarrying, incineration, chemical factories, smoke-stack emissions from power plants and manufacturing plants, smelters, open burning, residential heating, and tobacco smoke. Much of the fine particulate forms from chemical reactions among sulfates from power plants, nitrates from motor vehicles, and industrial emissions and ammonia from feed lots. A recent study of fine particulate from Ontario, Canada, showed that the composition was 30–50 percent organic and elemental carbon from burning (soot), 30–40 percent sulfate from sulfur dioxide,

10–20 percent nitrates from nitrogen oxides, and 3–10 percent soil, but this varies widely with season and location.

### ENVIRONMENTAL RELEASE AND FATE

Particulate size fraction of 50–100 micrometers is heavy and tends to settle out close to the source or be washed out by precipitation. Coarse and fine particulate, by contrast, can be transported over great distances in suspension by wind before settling to the surface. This process can result in acidic lakes and streams and alter the nutrient balance in coastal waters, lakes, and large river basins depending upon the composition of the particulate. It can deplete nutrients in soils and damage sensitive forests and agricultural crops. It can also destroy the balance in ecological systems. Fine particulate can cause reduced visibility and haze in urban, suburban, and rural areas.

### HUMAN EXPOSURE AND HEALTH EFFECTS

More than 99 percent of inhaled particulate matter is directly exhaled or trapped in the upper respiratory tract and then exhaled. Of that which is not expelled, coarse particulate can lodge in the lung tissues and slow the exchange of oxygen and carbon dioxide in the blood, causing shortness of breath. This condition is exacerbated by irritation and swelling of airways and can lead to life-threatening situations. Lack of oxygen strains the heart. Fine particulate can be absorbed directly into the bloodstream through the lungs. This process is even more damaging to the cardiovascular system. This condition is especially dangerous to people who have cardiac or respiratory disease such as emphysema, bronchitis, chronic obstructive pulmonary disease (COPD), and asthma. Some studies suggest that children and elderly adults are also more sensitive to particulate. Short-term exposure to particulate can cause coughing, wheezing, respiratory irritation, and painful and labored breathing. Depending upon the composition of the particulate, symptoms may be even worse. Long-term chronic exposure to particulate increases the risk of lung diseases such as emphysema, bronchiectasis, pulmonary fibrosis, cystic lungs, and lung cancer. It induces the progression of atherosclerosis, affects heart rate variability and blood lipids, and increases the likelihood of blood clots and stroke. It also damages the immune system in the lungs and, in general, contributes to premature death. It has been estimated that chronic exposure to particulate shortens a person's life span by as

much as two years. Exposure of pregnant women to high levels of particulate has been linked to preterm deliveries, low birth weight, and possible fetal and infant deaths.

### REGULATIONS ON HUMAN EXPOSURE

The first U.S. Environmental Protection Agency (EPA) restrictions for particulate matter were imposed in 1970, but they did not discriminate among the types. In 1987, the regulations were revised to discriminate between total particulate matter (TPM) from that of 10 micrometers or less ( $PM_{10}$ ) to address emerging research on health issues resulting from exposure to this finer fraction. In 1997, the regulations were further revised to separate even finer particulate of 2.5 micrometers or less ( $PM_{2.5}$ ), which caused additional health problems. The 1997 regulations limited coarse particulate ( $PM_{10}$ ) to an annual arithmetic mean of 50 micrograms per cubic meter of air and a 24-hour maximum of 150 micrograms per cubic meter, not to be exceeded more than once per year. Fine particulate ( $PM_{2.5}$ ) was not to exceed 15 micrograms per cubic meter of air on an annual basis averaged over three years and 65 micrograms per cubic meter for the 24-hour maximum. This standard could only be attained if the three-year average of the 98th percentile of 24-hour levels did not exceed the limit. In 2006, these standards were further revised to revoke the limits for the  $PM_{10}$  annual levels and to reduce the 24-hour  $PM_{2.5}$  maximal level to 35 micrograms per cubic meter of air. In 2005, the EPA designated nonattainment areas for  $PM_{2.5}$  standards. There are 39 nonattainment areas, which constitute 208 counties or parts of counties. The majority are east of the Mississippi River in the middle latitudes of the country (including nearly the entire state of New Jersey) and a large swath of California. By 2008, the states with nonattainment areas were required to submit plans to correct these problems, and by 2010, they were required to have implemented them, although extensions and exceptions were possible.

These National Ambient Air Quality Standards reduced the six criteria air pollutants by 54 percent between 1970 and 2004. There are several EPA programs that have helped this reduction, including the Clean Air Interstate Rule for power plants in the eastern United States; the Clean Diesel Program, which will reduce diesel particulate by 90 percent; and the Clean Air Visibility Rule, which reduces emissions that affect national parks. Coarse particulate was reduced by 25 percent between 1990 and 2005, although it has remained flat since 2003.

Fine particulate was reduced 7 percent between 1999 and 2005. Some scientists argue that the new standards are not stringent enough and may still allow as many as 20,000 deaths per year in the United States and leave 165 million Americans in areas with dangerous particulate levels. Direct intervention from the White House is blamed for the lax standards. The European Commission has instituted a two-phase reduction in particulate. Between 2005 and 2010, the yearly average could exceed 40 micrograms per liter of air, with a daily maximum of 50 micrograms not to be exceeded more than 35 days per year. After 2010, the maximal yearly average will be 20 micrograms per liter, with a daily maximum of 50 not to be exceeded more than seven days per year.

**particulate air control devices** There are a number of technologies that can be used to mitigate the effects of particulate releases from the burning of fossil fuels or during manufacturing processes. Modern boilers and manufacturing systems are designed to minimize the release of contaminants into the air. Many are computer operated and automatically adjust temperatures, feed rates, and oxygen/fuel ratios to maximize combustion efficiency. No system is 100 percent efficient, and to remove the particulate that is generated, physical separation and collection devices are needed. There are six basic types of particulate control devices.

### SETTLING CHAMBERS

Settling chambers are closed vessels where the waste gases are diverted to slow them and allow particulate to settle into a bin, or hopper, for collection and later recycling or disposal. This type of device relies on gravity to remove the particulate. They are typically used for larger particulate, that with a diameter of 10–50  $\mu\text{m}$ , because finer particulate would take too long to settle and require impracticably large chambers.

Settling chambers, also called gravity collectors, expansion chambers, or outfall collectors, are usually configured as long horizontal rectangular boxes with an inlet at one end and a discharge point (vent or stack) at the other. Inside the chamber are drag scrapers, or screw conveyors, that help collect and remove the settled particles. Although they have a low collection efficiency (less than 10 percent) for small particulate, settling chambers were a popular early method of air pollution control. They were inexpensive, reliable, and simple to operate.

Metal refining facilities used settling chambers to collect arsenic-laden particulate generated from the smelting of certain types of copper ores. Unburned carbon particulate or soot from coal-fired electrical generating stations and large commercial boilers was collected in settling chambers for reinjection into the furnaces. Today, the use of more efficient combustion technologies and the more stringent air pollution requirements of the 1960s and 1970s have made the use of settling chambers as a primary air pollution control device rare. Not many remain in commercial operation, and most are relegated to the status of “precleaners,” removing large particulate prior to the routing of the waste gas to another treatment device.

### CYCLONES

Cyclones are devices that force particulate entrained in a waste gas into a special cone-shaped cylinder. Cyclones can be designed with one large chamber or consist of a series of smaller, interconnected tubes or partitions. Regardless of the design, the basic operating principal requires the gaseous waste stream to be blown downward as it enters the cyclone. Centrifugal force pushes the particulate in the waste stream onto the walls of the cylinder, where it falls to the bottom for eventual collection and disposal. The now-treated gas then is discharged out of the cyclone. Cyclones are inexpensive, easy to install and operate, and fairly maintenance-free. Particulate is collected in dry form so that it can be reused in the manufacturing process, recycled, or disposed of at an approved facility.

A good example of how cyclones are used to control air emissions is at Wolverine Bronze, a metal foundry in Roseville, Michigan, about 20 miles (32 km) north of Detroit. In order to cast liquid metal into various shapes, a pattern is created by using material called foundry sand. Made up of clean, uniformly sized high-quality silica sand that is bonded usually with clay or a special chemical, foundry sand is used to form molds for ferrous, aluminum, bronze, and other types of metal castings. The iron and steel industries use about 95 percent of the foundry sand produced in the United States for making automotive parts, structural beams, and machine parts. The sand is expensive, and over time it becomes contaminated with binding agent as well as bits and pieces of the metals that are poured into it.

Most foundries recycle the sand by pouring it into a shaker that breaks up the sand lumps and sieves out the metal particles. The sand is then heated to burn off residual casting binder. As the sand is handled, dust is given off and can create both a worker and environmental hazard. At Wolverine Bronze, the foundry sand recycling system generates about four tons (3.6 metric tons) of sand per hour and typically operates as long as 13 hours per day, generally at night and weekends, when electrical rates are low. Dust from the recycling system is collected and managed by a three-stage system. A sieve is used to screen out the larger particles, with the exhaust fumes sent to a cyclone for separation of finer material. Finally, the remaining fines are passed through a baghouse before the carrier air is discharged. Wolverine Bronze has operated this system for more than 10 years with no violations of its air permit limitations.

Cyclones work best on particulate larger than 10 micrometers; smaller size particulate (PM<sub>2.5</sub>) tends to remain in waste gases. High-efficiency cyclones that are available can collect particulate as large as 5 micrometers, but these are more expensive and difficult to operate and maintain. For these reasons, cyclones generally are used as pretreatment or pre-cleaning devices, removing larger particulate and conditioning the waste gas for treatment by more aggressive processes. Air emissions from mineral and chemical industry processes involving crushing, grinding, and calcining (heating) often are pretreated with cyclones. Emissions from fossil fuel-fired boilers or furnaces typically are discharged to a series of cyclones prior to treatment by fabrication filtration, scrubbing, or electrostatic precipitation.

### FABRIC FILTRATION (BAGHOUSES)

Fabric filters are essentially giant vacuum cleaner bags. The waste gas is forced through a series of

**Cutaway diagram illustrating a vertically mounted cartridge baghouse. Contaminated air enters the port on the left side and is driven through the vertical filter cartridges and the manifold before exhausting through the port on the front. Particulate can drop into the hopper beneath for collection.**

cloth filters (bags or cartridges) that physically separate the particulate from the gas stream. Filters are most commonly made of fabric but can be any coarse, granular substance that effectively traps particulate. Materials used include cotton, wool, nylon, and polypropylene; Teflon®, Nomex®, and fiberglass have also been fabricated into filters for use in specialty high-temperature or corrosion applications. Filters are wrapped around hollow tubes and arranged in rows to provide a large surface area through which the waste gas passes. The filters, tubing, and associated blowers and vents are big and noisy, and they are usually placed in separate, stand-alone structures, called baghouses.

Capture efficiencies of more than 95 percent for 0.5- $\mu\text{m}$  particulate are achievable. After the solids are removed, the cleaned gas is discharged into the atmosphere. Particulate is removed from the filters by shaking them or by back-flushing, which involves reversing the flow of air and blowing it through the filters from the other direction. The particulate is collected in a hopper or drum and is either disposed of or recycled.

Although there are many industries that generate particulate during their operation, the processing and production of taconite present a particulate challenge to the effective management and control of dust and fines. Taconite is a variety of chert, a light-

colored silica mineral mixed with magnetite and hematite, both of which contain iron. Almost all the iron ore remaining in the United States is taconite, and most is from the Upper Peninsula of Michigan. To extract the iron, the taconite is crushed and ground into small particles. The iron is then recovered by using magnets or gravity separation because the iron minerals (magnetic and hematite) are much heavier than the silica mineral (chert). Enormous quantities of particulate are produced by these crushing and grinding operations, and particulate must be prevented from entering the atmosphere, where it can adversely affect local air quality, compromise the health of mill employees, and damage expensive processing equipment.

At the taconite mine and mill in Babbitt, Minnesota, 200 miles (322 km) north of Saint Paul, engineers installed a fabric filtration system to control dust at the truck dump pit, where the processed ore is loaded for shipment, and at the primary crusher, the largest in North America. Once installed, the system was successful in reducing dust in the loading area by 50 percent, and air emissions were substantially below U.S. Environmental Protection Agency (EPA) regulatory limits.

Baghouses are expensive to build and maintain, and fabric filtration is not effective in humid environments. They commonly are used with waste gas

streams that tend to be dry such as at cement plants, steel mills, and quarry processing. Fabrics can be damaged if waste gas temperatures are too high or if the air emissions to be treated contain combustion or processing by-products that are acidic. In high-volume settings, fabric filtration is at a disadvantage when compared with other air pollution control technologies because of the large pressure drop that occurs when the waste gas is forced through the filters. This pressure drop slows gas discharge rates; increases energy demand because the motors, blowers, and other equipment have to work harder; and can cause premature wear or damage.

### SCRUBBERS

Scrubbers use a liquid, usually water, to remove particulate from a waste gas. Water is sprayed into the waste gas as it flows up the exhaust stack or process vent. The water droplets surround and trap the particulate, washing it down into a collection device for later treatment. Some scrubbers are designed to increase the size of the particulate, by combining it with a water droplet. This droplet is then removed in another waste gas treatment step. The ability of a scrubber to remove particulate decreases as the particle size decreases. More water is needed to remove smaller particles from the waste gas. Scrubbers are

**Cutaway diagram of an electrostatic particulate removal system. Particulate adheres to charged metal collection plates as it passes through and drops into hoppers below.**

often used in combination with cyclones, with water jetted into the cyclone to help capture and wash down the particulate.

Depending on their design, scrubbers can treat flammable or explosive dusts, cool waste gases prior to discharge, and neutralize acidic mists and vapors. At the top of the stack, or discharge vent, demisting devices are installed to prevent very fine droplets of water (aerosols) created during the scrubbing process from being carried out with the exhaust gas.

For one company in Ohio, the installation of a scrubber to treat emissions from its industrial furnace solved two problems. Teflon-coated baking trays are refurbished at the plant by first baking off the nonstick coating at high temperatures in a furnace. This produces particulate in the 5- $\mu\text{m}$  range as well as hydrofluoric acid, a very corrosive substance. To remove the fine dust and soot from this process waste gas stream, the company installed a scrubber. In addition to a particulate removal efficiency of 99 percent or better, a strong base (sodium hydroxide) was mixed with the scrubber solution. The solution, which was continuously recycled during off-gas treatment, was successful in neutralizing the acid and significantly reduced equipment corrosion.

Large amounts of clean water are needed to operate scrubbers, and the waste liquid and/or resulting sludge needs to be treated and disposed. Capital and operating costs associated with the installation and use of wet scrubbers are high, and most industries tend to use scrubbers only when other waste gas treatment technologies cannot meet required treatment levels. Scrubbers are used to control particulate releases from utility, industrial, and institutional boilers fueled by coal, oil, wood, and even used oil. They also manage emissions from the chemical, mineral products, pulp and paper, and other manufacturing industries, as well as municipal solid waste (trash) incinerators.

### ELECTROSTATIC PRECIPITATORS (ESPs)

ESPs are among the most effective means of removing particulate from a waste gas. Operating on the simple principle that positively and negatively charged particles are attracted to each other, ESPs are large electrically charged metal plates that line the smokestack or exhaust vent. As the waste gas enters the stack, it passes through negatively charged wires or rods and is ionized. It then flows past a positively charged collection plate, where the particulate is removed from the waste gas without affecting its flow-through velocity. The collection plates are cleaned periodically of accumulated particulate

**Cutaway diagram of a cyclone particulate control device in which particulate is liberated from contaminated air by centrifugal force as it spins around the metal tank**

by automatically operated rappers, small mallets or hammers that gently bang on the collection plates, loosening the particulate and letting it fall into a hopper for collection and recycling or disposal.

ESPs work well in high-volume gas settings (up to 4 million cubic feet per minute [113,267 m<sup>3</sup> per minute]) and can collect submicron (<1  $\mu\text{m}$ ) size particulate. They are very energy efficient and are not bothered by relatively high temperature gases (as high as 1,200°F [649°C]). Collection efficiency typically ranges from 98 to 99 percent. One disadvantage of ESPs is that they are large. The waste gas moves through the system at velocities in the range of meters per second, but the particulate is attracted to the collection plate at velocities only in the range of meters per minute. This means that the collection chambers have to be big and are sized on the basis of anticipated discharge velocities. Despite this drawback and the fact that ESPs are expensive to design and install, they are widely used in industrial applications, especially in coal-fired power plants.

Newport Towers is an upscale commercial building on Jersey City, New Jersey's, "gold coast" waterfront and has spectacular views of the Manhattan skyline. One of the many amenities the building features is a large cafeteria for tenants and guests. Smoke generated by cooking produces particulate between 0.3 and 0.8  $\mu\text{m}$ . To maintain the fashionable look of the building and to be a good neighbor, Newport Towers installed a heavy-duty, three-pass electrostatic precipitator (ESP) system. In this system, emissions from kitchen stoves and ovens pass through three ESPs, each controlled by a microprocessor that makes automatic adjustments in electrical charging and, therefore, very high particulate capture rates, resulting in no visible emissions from the building. The ESP system was easy to install, and maintenance (cleaning) is needed only once a year.

Desirable characteristics such as these account for the wide use of electrostatic precipitators by industry, especially in the electrical power-generating field. In addition, the energy expended in separating particulate from a waste gas stream by means of an electrostatic precipitator acts solely on the particulate, and not on the gas stream. This is unique for collection equipment in the air pollution field, since other devices based on different principles of separation require that energy be expended on the entire gas stream in order to achieve the desired effect.

**Patterson, Clair Cameron "Pat" (1922–1995)** *American Chemist, Geologist* Clair Cameron "Pat" Patterson made an amazing contribution to the environment and public health: He almost single-handedly eliminated all commercial uses of lead. What is even more amazing is that he had no training as a politician or advocate; he was a soft-spoken man of simple means and an excellent scientist. In many of the political issues that involve science, warnings from scientific data are used by advocates mainly as conveniences to prove a point in some larger struggle. In other cases, they are only used if there is no other choice. In this case, against all odds and personal and professional attacks, Patterson stood his ground that lead was overused and dangerous, citing his own meticulous scientific studies, and, in the end, he prevailed.

#### BIOGRAPHICAL INFORMATION

Pat Patterson was born on June 2, 1922, in the small town of Mitchellsville, Iowa, near Des Moines. He attended a small rural high school with fewer than 100 students and graduated in 1940. He earned a bachelor of arts degree in physical chemistry from Grinnell College, Iowa, in 1943. It was there that he met and married his wife, Lorna McCleary. Patterson earned a master's degree in 1944 from the University of Iowa in chemistry, specializing in molecular spectroscopy. His thesis adviser, George Glockler, invited him to the University of Chicago to work on the Manhattan Project to help develop the atomic bomb. After several months, Patterson decided to enlist but was rejected because of his high security clearance. Instead, he was transferred to Oak Ridge, Tennessee, to continue work on the Manhattan Project. It was there that he became familiar with mass spectrometry of uranium isotopes. By accelerating uranium atoms along a magnetized flight tube, masses of the various isotopes can be determined. Isotopes of an element have the same number of protons and electrons and, therefore, the same name but varying numbers of neutrons; thus, the atomic mass varies. About 25 percent of isotopes of elements are radioactive. Uranium has several radioactive isotopes.

After the war, Patterson returned to the University of Chicago to earn a Ph.D. As a result of his experience with mass spectrometers, Harrison Brown, his adviser, assigned Patterson a dissertation on lead isotopes in 1948. He developed the first isotopic methods to determine the age of rocks for his dissertation in 1951 by using a mass spectrometer. To accomplish this, he had to devise laboratory procedures and in

Clair C. Patterson, 1972 (Archives, California Institute of Technology)

the process found that background levels of lead were much higher than he had expected. He had to develop procedures to keep the lab ultraclean or the samples for study would immediately become contaminated by ambient lead.

Patterson remained at the University of Chicago as a postdoctoral fellow under Brown, but then followed him to the California Institute of Technology the next year. Patterson turned his attention to lead isotopes in meteorites and, in 1953, determined that all meteorites have the same age. This discovery was a breakthrough because it meant that meteorites all formed at the same time. The only event that could link all of these objects from such distant parts of the solar system was the formation of the solar system. Patterson was able to report that the age of the Earth and solar system was 4.55 billion years as a result of this work. This discovery was hailed as one of the greatest in the 20th century by the scientific community. Even more impressive is that with all of the additional research and better orders-of-magnitude technology, this age still stands today.

For any other scientist, such a momentous discovery would have been more than enough for a

whole career. Patterson, however, who was now a faculty member at Cal Tech, was not satisfied. He began characterizing common geological materials in terms of their lead contents and isotopes. It would be this work that would lead to his concern about anthropogenic lead.

### BATTLE AGAINST ANTHROPOGENIC LEAD

As the result of his great efforts to build a "clean lab," where he could analyze small quantities of lead, and his characterization of lead contents of normal geological materials, Pat Patterson realized that there was an inordinate amount of lead in the modern environment. By 1962, Patterson and his colleague Tsaihwa Chow showed that anthropogenic lead was being deposited at the astounding rate of 80 times that in the oceans. In 1963, he showed that surface water contained three to 10 times as much lead as deep ocean water, whereas, as with other heavy elements, it should have been much less. The first direct strike at industry occurred in 1965, when he published a meticulous study titled "Contaminated and Natural Environments of Man." It showed that, in

contrast to the common conception that industry increased exposure to lead no more than twofold, Americans were being exposed to lead at 100 times natural levels (within one-half the level of outright lead poisoning.) These levels were found within the blood of the volunteers. He identified gasoline (leaded), paint, solder in pipes and electrical devices, and pesticides as the main industrial sources. With Patterson's reputation as an eminent scientist, these findings were taken seriously by the scientific community, although there was some skepticism.

As a result, Patterson was attacked both personally and professionally as a zealot and a rabble-rouser rather than a scientist by respected industry professionals. The attacks did not dissuade him. Instead, he wrote to Governor Pat Brown of California on October 27, 1965, warning him about lead in the air, especially in the Los Angeles area. This first attempt was politely rejected. He had also sent a similar letter to Senator Edwin Muskie, the chairman of the Subcommittee on Air and Water Pollution, on October 7, 1965. As a result of this letter, Patterson was invited to testify at a hearing in Washington, D.C., on June 15, 1966. Perhaps encouraged by the success on the national front, Patterson sent a second letter to Governor Brown on March 24, 1966, which was better received. On July 6, 1966, the California Department of Public Health was ordered to establish air quality standards by February 1, 1967.

All the success in advocacy could have dissuaded Patterson from his research, but instead, he increased his efforts to collect data to support his convictions. In 1970, he released a paper in which he studied lead in ice cores from both Greenland and Antarctica. He found that lead level in snow from Greenland was 100 times as great at that time as it had been in preindustrial times. The Antarctic data showed a 10-fold increase largely because there is less land, fewer people, and less industry near the Southern Pole. Despite these findings, the National Research Council released a subsequent report on airborne lead that largely ignored Patterson's work. Again, this did not stop him, and in 1973 he showed that lead from the burning of gasoline was permeating even the most remote wilderness areas. Whether it was this study, the whole barrage of Patterson's work, or the growing public support, the EPA announced in December 1973 that there would be phased reduction of lead in gasoline of 60–65 percent. Patterson's findings were finally being recognized, and success did not slow his efforts. He continued to collect data, showing in 1975 that high concentrations of lead could overwhelm a plant's natural defenses that would exclude it from their tissues. Perhaps the most

interesting of his studies was the 1979 comparison of 1,600-year-old Peruvian skeletons with modern human bones that showed an increase in lead level of 700–1,200 times in modern humans. Patterson's next target was the removal of lead from food. In 1979, he informed the EPA that their methods were not sensitive enough to test properly for lead in tuna. On October 10, 1981, Patterson participated in a symposium on this issue in Washington, D.C., which was attended by the EPA and Bureau of Foods. Within a few months, the EPA was meeting Patterson's standards. In 1980, Patterson participated in a study that showed excessive levels of lead in canned goods from the solder used in sealing the lids. By 1991, all lead had been removed from cans, as well as paints, water lines, and gasoline, among other materials, and the lead content of new-fallen snow in Greenland had decreased by a factor of 7.5 relative to that of 1971. Patterson almost single-handedly had greatly enhanced public health.

### RECOGNITION AND AWARDS

Pat Patterson's achievements were not unnoticed by the scientific community and the world. He was a member of the National Academy of Sciences and was awarded their J. Lawrence Smith Medal in 1973. He was also the 1995 Tyler Prize laureate for environmental achievement, among many other honors. Perhaps the most impressive recognition was the naming of asteroid 2511 after him as well as a mountain peak in the Queen Maude Mountains of Australia. He even served as the model for the character Sam Beech in the Saul Bellow novel *The Dean's December*. Very few scientists, no matter how great their achievements, have received such honors.

### IMPACT ON SOCIETY

It is rare for one person to have such an impact on an environmental issue. Other environmental pioneers such as Rachel Carson and Roger Randall Daughan Revelle identified a problem and called it to public attention. Pat Patterson is unique in that he identified a major problem and saw it completely through to resolution. Gasoline, paint, and pipe solder are now all lead-free as a result of the work of Pat Patterson, which is also the reason children are now tested for lead poisoning.

Pat Patterson retired from the California Institute of Technology in 1987 but remained active in both his research and activism. He died of asthma on December 5, 1995, at his home in California.

**PCBs (polychlorinated biphenyls)** According to the U.S. Environmental Protection Agency (EPA), PCBs are among the most widely studied environmental contaminants. In 1976, in large part as the result of the persistence and toxicity of PCBs in the environment, the U.S. Congress enacted the Toxic Substances Control Act, which specifically prohibited the manufacture, processing, and distribution of PCBs. The reasons for all of the concern are the documented and widespread adverse health effects. They are known carcinogens for animals and strongly suspected to be carcinogens for humans. They also have been shown to have strongly adverse effects on the immune system, the reproductive system, the nervous system, and the endocrine system in animals and humans. Their chemical stability and persistence in the environment make them especially dangerous.

PCBs occur in significant quantities in at least 500 of the first 1,598 hazardous waste sites (Superfund sites) on the EPA National Priorities List (NPL), making them an important contaminant of concern in the United States. As a result of their widespread distribution and adverse health effects, PCBs are ranked as the fifth worst environmental pollutant of the 275 listed on the 2007 CERCLA Priority List of hazardous substances.

One of the most famous cases involving PCBs is the dumping of between 209,000 and 1.3 million pounds (94,800 and 590,000 kg) of PCBs into the Hudson River of New York by the General Electric Company. The PCBs originated at two capacitor factories at Hudson Falls and Fort Edward, New York, and turned 200 miles (120 km) of this important

river into a designated Superfund site. As a result, fishing was banned in the Upper Hudson from 1976 to 1995, but it was renewed on a catch and release basis. General Electric argued that dredging the river would release more PCB into the environment than leaving it sequestered in the sediments. The EPA did not agree, and the final resolution was in late 2006, when it was agreed that dredging would begin in 2008.

## PROPERTIES, USES, AND PRODUCTION

Polychlorinated biphenyls are a group of mixtures of manufactured organic chemicals that form 209 individual compounds, called congeners. They range from viscous oily liquids to waxy solids that are colorless to light yellow, although some can exist as vapor in air. PCBs have no taste or smell, and they are soluble in most organic solvents, oils, and fats. They were regarded as miracle substances when they were invented, in the late 1920s, because of their inflammability, chemical stability, high boiling point, and electrical insulating properties. The main use of PCBs was as a cooling and insulating fluid for industrial transformers, capacitors, and other electrical equipment. They were produced by Monsanto from 1930 to 1977 under the trade name Aroclor and by General Electric as Pyranol. Other names include Chlorinated diphenyl, Clophen, Kanechlor, Fenclor, Chlorextol, Dykanol, Inerteen, Monter, Pyralene, Santotherm, Sovol, Therminol, and Noflamol. They were used in hundreds of industrial applications including electrical, heat transfer, and hydraulic equipment; household appliances; plastic and rubber products; plasticizers in paints, pigments, and dyes; microscope and other oils; adhesives and sealants; and copy paper. By the time production of PCB ended in 1977, more than 1.5 billion pounds (682 million kg) had been manufactured in the United States alone. It is literally everywhere and will take decades to eradicate completely from regular use, much less from the environment.

## ENVIRONMENTAL RELEASE AND FATE

PCBs entered the natural environment during their manufacture through air, water, and soil from accidental spills and leaks. They have continued to enter the environment through leaks in operational devices that contain PCBs and disposal methods, either illegal or from leaky older hazardous waste sites. Incineration of PCB products under improper conditions may also release it into the environment. Once PCBs are in the natural environment, they are very difficult to remove. They are chemically

stable, so they persist for a long time and may be transported long distances from a spill site without alteration. Although PCBs may remain dissolved in water for long periods, they have a tendency to bind strongly to organic compounds in soils and bottom sediments. Their chemical stability also allows them to bioaccumulate in aquatic organisms. By the time PCBs reach the top of the food chain, they may be thousands of times more concentrated in the fish and marine mammals than they are in the surrounding water. People who eat fish that inhabit PCB-tainted waters are at great risk for poisoning.

Disposal of PCBs can be done by physical, microbial, and chemical processes. PCBs have been placed into landfills in large quantities, primarily in the form of transformers and capacitors. Incineration of PCB-bearing waste is another form of disposal, but they must be burned at temperatures of 2,192°F (1,200°C) or more for at least two seconds in the presence of fuel oil and an excess of oxygen. Improper incineration of PCBs can result in the formation of other dangerous compounds such as dioxins in addition to remnant PCBs. Ultrasound can also be used to destroy some PCB congeners if they are water soluble and have low chlorine content. Gamma irradiation can destroy PCBs in the presence of mineral oil or isopropanol. These destructive physical methods tend to be complex and relatively expensive. Microbial methods are also not without complications and expense. Bacteria tend to be selective as to which compounds they will dechlorinate, and even when they are effective, they tend to be very slow. Although bacteria may be effective in dechlorinating PCBs in laboratory conditions, they are typically much less effective in natural settings. The numerous chemical methods for PCB destruction are also only partly effective and only under specific conditions. They are typically quite costly. In many cases, the affected soil, dredge sediments, or water is simply removed and stored.

### TOXICITY AND HEALTH EFFECTS

Long-term exposures of rats to PCBs have resulted in a significant increase in liver cancer. Studies of workers exposed to PCBs similarly found increases in rare liver cancers, as well as malignant melanoma, but several others were inconclusive. It is suspected that other factors such as smoking and alcohol consumption may exacerbate the effects. Studies on monkeys and other animals found significant effects of PCBs on the immune system including a decrease in size of the thymus gland, reduction in response of the immune system to standard stress tests, decreased resistance to Epstein-

Barr virus, and increase in viral infections including pneumonia. Humans have a similar response to PCB exposure including increased risk of Epstein-Barr virus and non-Hodgkin's lymphoma. The effects of PCBs on reproductive systems of monkeys and other animals include low birth weight, conception rates, and live birth rate, as well as low sperm counts among rats. Fish apparently have the same problems. These effects are long term even long after exposure has ended. Babies of women exposed to PCBs during factory work showed similar low birth weight and significant decrease in gestational age. When newborn monkeys are exposed to PCBs, they show significant long-term decrease in neurological development including learning, short-term memory, and visual recognition. Human babies show similar learning deficits, problems with motor skills, and neurobehavioral problems. The endocrine disruption from PCB exposure includes decreased thyroid hormone levels, reducing normal growth and development, as well as hearing loss in animals and probable similar effects on humans. Other effects on humans and animals include acne-like skin conditions, anemia, and ocular effects; elevations in blood pressure and serum triglyceride and serum cholesterol levels; and various degrees of liver and stomach toxicity in rodents and other animals. PCBs tend to be concentrated in human breast milk, providing an even more dire threat to children.

### REGULATIONS ON HUMAN EXPOSURE

As a result of these significant adverse health effects, many federal agencies have imposed limits on human and environmental exposure to PCBs. The EPA limits PCBs in drinking water to less than 0.5 part of PCBs per billion parts (ppb) under the Safe Drinking Water Act. The EPA further regulates the level of PCBs in lakes and streams to no greater than 0.17 part of PCBs per trillion (ppt). By law, industrial releases of one pound (0.45 kg) or more of PCBs into the environment must be reported to the National Response Center. The U.S. Food and Drug Administration (FDA) limits the content of PCBs in food including 0.2 part per million (ppm) in infant and junior foods, 0.3 ppm in eggs, 1.5 ppm in milk and other dairy products, 2 ppm in fish and shellfish, and 3 ppm in poultry and red meat. Several states and local jurisdictions have their own regulations regarding PCBs, especially with regard to fish and wildlife consumption. The Occupational Safety and Health Administration (OSHA) limits exposure for workers to less than 1 mg per cubic meter of air (mg/m<sup>3</sup>) over a period of eight hours for five days

per week for 42 percent chlorine PCBs, or 0.5 mg/m<sup>3</sup> for 54 percent chlorine PCBs. The National Institute of Occupational Safety and Health (NIOSH) recommends that workers not breathe air higher than 1 microgram per cubic meter of air (mcg/m<sup>3</sup>) for 42 or 54 percent chlorine PCB levels over a 10-hour-workday, 40-hour workweek. In the 1981–83 NIOSH National Occupational Exposure Survey, only 13,871 workers were exposed to PCBs in the workplace, mainly because it had been banned from most applications by then.

**PCE (tetrachloroethylene)** Also commonly known as perc, PCE gained fame from its portrayal in the popular movie *A Civil Action*, which centers around a lawsuit over a cluster of leukemia cases, ostensibly in Massachusetts. The reality is that PCE is one of the most widespread contaminants, affecting virtually everyone to some degree, and, as such, is a significant environmental concern. PCE is a synthesized compound that is classified as a halogenated aliphatic hydrocarbon, and it is used primarily as a solvent in many applications. It is also a hazardous chemical that is toxic to humans and a threat to the

environment. PCE is also known as Ethylene tetrachloride, Perchloroethylene, Ankilostin, Didakene, Fedal-un, Nema, Percdene, Persec, Tetlen, Tetracap, Tetraleno, Tetropil, Antisal 1, Dow-per, Perawin, Perchlor, Percosolv, Perklone, Tetraguer, Tetralex, and Tetravec. PCE has been identified in 771 of the first 1,430 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) in which it was tested. This is a very high percentage relative to other pollutants in such sites. The widespread nature, toxicity, and other physical characteristics led PCE to be rated as the 31st most hazardous pollutant on the 2007 CERCLA List of the top 275 pollutants.

### PROPERTIES, USES, AND PRODUCTION

PCE is a colorless, strong-smelling, volatile liquid, which is categorized as a dense nonaqueous-phase liquid (DNAPL). In the 1970s, PCE was used 58 percent for dry cleaning and textile manufacture, 18 percent for metal cleaning, 12 percent in chemical production, and 12 percent for miscellaneous uses. By the mid-1990s, usage had shifted to 55 percent for dry cleaning and textile manufacture, 11 percent for metal cleaning, 29 percent in chemical production, and 5 percent for miscellaneous uses. Through the 1990s, PCE use in dry cleaning decreased by 60 percent so that by 2000, 21 percent was used for dry cleaning, and 50 percent was used in chemical production. Chemical production is primarily as an intermediate in the manufacture of refrigerants and in production of alkalis and chlorine, among others. The miscellaneous uses include insulating fluid and cooling gas in transformers; as a component of paint removers, printing ink, adhesives, paper coatings, and leather; as an extractant in pharmaceuticals; and in aerosol applications such as water repellants, automotive cleaners, silicone lubricants, and spot removers.

PCE was first synthesized in 1821, but commercial production in the United States did not commence until 1925. In 1941, production in the United States was 1.1 million pounds (1 million kg), and it increased steadily to a peak of 763 million pounds (347 million kg) in 1980. Production then decreased steadily through 1996, to 280 million pounds (127 million kg), as the result of environmental restrictions. Production then increased slightly through 1999 and 2003 to 318 million pounds (145 million kg) and 340 million pounds (155 million kg), respectively. Imports declined from the 1980s, when they were typically in the range of 132–140 million pounds (60 to 63 million kg) per year, to an average of 80 million pounds (36 million kg) per year from

## DRY CLEANING AND THE ENVIRONMENT

Fabrics or woven fibers have a number of advantages over the furs, grasses, and shells that were worn prior to their development. Lighter weight and more flexible, they gave people a better variety of choices on how to protect themselves from the weather. Wool, linen, cotton, hemp, and other fibers became widely and reliably available with the domestication of animals and the formation of stable agricultural communities. Although highly automated today, cloth production remains one of civilization's most basic technological advances. Thought to have been developed from the same techniques used in basket making, it is a four-step process.

First the fiber (wool, cotton, etc.) must be collected or harvested. After removal of foreign matter such as dirt, plant, or animal debris, the fibers are then aligned and spun into thread. This thread is then woven into cloth or fabric. Finally, the fabric is cut and shaped into clothing. For almost 10,000 years, that is how fabrics were made, with coloring, blending of fibers, and mechanization introduced as new techniques were developed. One of the most radical advances in cloth production took place in the 1920s and 1930s with the introduction of synthetic fibers such as nylon, rayon, and finally polyester in the 1950s, all made from petroleum products.

### WASHING FABRIC

The development of clothing presented the problem of how to keep it clean. Clothing soiled with dust, grime, body oil, and sweat attracted insects, lost its flexibility and some of its ability to protect against the elements, and became generally uncomfortable and unpleasant to wear. When this happened to an animal skin or grass skirt, the user simply discarded it and went hunting or assembled another. Cloth production, on the other hand, was a highly specialized and time-consuming skill; people did not lightly discard a shirt or blanket that had taken weeks or even months to make.

Ancient Egyptian and Mayan pictographs show people cleaning their clothing in a river or stream, letting the running water carry away the dirt and grime. In many developing countries, clothes are still cleaned in this manner. Agitation helped remove the stains and smells, so clothing was twisted and rubbed, even pounded against rocks. After washing, the cleaned materials were spread out on the grass to dry in the sunshine. Over time, rocks were replaced with corrugated washboards, and the cloths were hung up in the breeze to allow them to dry faster and to prevent insects from infesting them. In water-poor areas where streams were scarce, wash water was placed in tubs and its

solvent effect was increased through the use of soaps, which were lye leached from wood ash and added to fat or extracted from soaproot or yucca root plants.

Warm water was found to increase the effectiveness of soap, so metal washbasins began to be heated over a fire. By the 1700s, the laundry mangle, or clothes wringer, had been invented to press out excess water and smooth the fabrics being washed. This hand-operated mangle was often combined with a similarly operated paddle inside the washing tub. By moving the paddle, cloth could be agitated and mixed with soap remotely and in larger volumes. With the development of the electric motor in the late 1800s, it was not long before both of these manually operated devices had been replaced with the washing machine.

As fabrics and designs became more complex, and the uses of clothing grew to include not only functionality but also appearance and status, a simple soap and water washing was no longer sufficient. Commercial laundries, which began to appear in the 1700s and 1800s, tried a variety of products to remove stains and improve the appearance and feel of fabrics. Gasoline and kerosene excelled at removing food stains such as grease and bodily oil and sweat residues but were dangerous to work with and the final product tricky to wear for a smoker. In the early 1930s, an Atlanta laundry owner, W. J. Stoddard, working with a chemist from the Mellon Institute developed a much less flammable alternative to kerosene and gasoline called Stoddard Solvent or White Solvent. It became the cleaning fluid of choice until the 1950s. A transparent liquid derived from paraffin, Stoddard Solvent was gentle on fabrics and much less flammable than the petroleum hydrocarbons then in use.

### DRY CLEANING

Shortly after World War II, a new class of industrial degreasing compounds began to emerge. Organochlorides were inexpensive, easy to make, and immiscible in water. An organochloride is an organic compound that contains at least one covalently bonded chlorine atom and has widely diverse chemical structures and properties. One, in particular, a chlorinated hydrocarbon named tetrachloroethylene, also called perchloroethylene (PCE), or perc, would prove to be ideal for use in dry cleaning. Starting in the 1950s, perc gradually replaced Stoddard Solvent and today is used almost universally in the dry cleaning of clothes.

Although soap and water is a useful solvent for many clothes, this combination does not work as effectively with some fabrics such as wool or with some stains

such as grease. Dry cleaning is a process that uses a nonwater solvent such as perchloroethylene to remove stains and bodily residues from clothes and fabrics. In dry cleaning, material is washed in perchloroethylene rather than water. After washing, most of the perc, which is easily evaporated, is recovered in an extractor, a type of distillation unit that filters it and allows it to be reused. The clothes are then pressed and are ready to wear. As almost no water is used in the solvent washing process, the term dry cleaning came into use. The sweet odor that is present when the plastic bag is removed from freshly dry cleaned clothes is that of evaporating perc. One U.S. Environmental Protection Agency (EPA) study estimates that there are 35,000 commercial dry cleaning operations in the United States, which process more than 640,000 tons (581,818 metric tons) of clothes annually. In 2006, these dry cleaners, along with industrial degreasing activities, primarily those associated with metalworking and electronics manufacturing, used 20.5 million pounds (9.3 million kg) of perc in their operations.

### **DANGERS OF DRY CLEANING**

As with almost all industrial products or materials that contribute to the quality and convenience of modern life, the use of perc has an environmental consequence. Although perc is physically much safer than those earlier dry cleaning compounds such as gasoline and kerosene, high airborne concentrations of perc (in the 100,000 mcg/m<sup>3</sup> range), especially when encountered in poorly ventilated areas, have an anesthetic effect, causing dizziness, headache, and nausea. If exposure continues, it can lead to difficulty in speaking and walking, unconsciousness, and eventually death. This most often occurs in occupational settings. Perc has been designated as a potential human carcinogen by the U.S. Department of Health and Human Services on the basis of an increase in liver tumors in mice and kidney tumors in male rats from exposure. Other government agencies and many states consider perc more toxic and require it to be managed aggressively in the workplace. Almost 80 percent of the perc discharged into the environment is via the atmosphere.

Although recent improvements in dry cleaning equipment have helped reduce the amount of perc escaping into the air, it is still a commonly detected air pollutant. Concentrations can vary widely with wind direction, speed, and distance from the emission source; several studies in the United States and Canadian urban areas have reported atmospheric ambient perc concentrations in the range of 0.2–9 mcg/m<sup>3</sup>. Higher values were reported near dry cleaners and certain types of waste processing or disposal facilities,

and lower values found in more rural areas. Human health implications associated with the long-term inhalation of perc at these low levels are not known.

Perc released as a liquid enters the soil and has been shown to damage vegetation. It also can be taken up and stored in the fatty tissue of some animals, thus entering the food web. The real risk posed by the release of liquid perc occurs when it enters the groundwater. Perc has a density of 1.6 g/cm<sup>3</sup> and, therefore, tends to move downward through the groundwater and accumulate as pools or pockets on top of the bedrock or less permeable layers. These pools or pockets of perc dense nonaqueous phase liquid (DNAPL) can continue to pollute groundwater for years after the initial spill and overlying contaminated soil have been remediated. DNAPL pools or layers are very difficult to locate and address. Because it is resistant to bacterial degradation and often accumulates far below the land surface, perc DNAPL is not easily recovered by conventional in situ or ex situ soil or groundwater remedial technologies.

The most common way liquid perc was released from dry cleaning operations, prior to today's strict environmental controls, was during the cleaning or maintenance of equipment, when spent or off-spec perc was simply dumped or poured into a storm drain or onto the ground in back of the shop. Also, toward the end of the dry cleaning cycle, perc-containing cleaning fluid is separated from the small amount of water also used in the process via a distillation unit built into the dry cleaning machine. In the past, this water, which contained residual amounts of perc, was often poured down floor drains or out onto the ground. In the more modern equipment being used today, the wash water is evaporated or removed and collected for processing at a hazardous waste disposal facility. Liquid perc also can escape into the environment via spills or seepage from aboveground or underground pipes, storage tanks, broken or damaged machine process lines, or perc-bearing wastes that have been disposed of improperly.

### **AN EXAMPLE FROM NORTH CAROLINA**

The impacts of perc from dry cleaning operations are amply illustrated at the ABC One Hour Cleaners Site located in Jacksonville, Onslow County, North Carolina. This small property is an active dry cleaner located across the street from Camp Lejeune Marine Corps base, and was in business since the early 1950s. Facility operators had followed standard industry practices in effect at that time for management

*(continues)*

(continued)

of perc wastes and residues. They pumped them into septic tanks, dumped them on the ground, and even used them to fill potholes on the property. In 1984, routine sampling by the U.S. Navy found that three water supply wells owned by Camp Lejeune had been contaminated with perc and its breakdown products trichloroethene (TCE), 1, 2-dichloroethene (DCE), and vinyl chloride. The source of this contamination was quickly traced to the ABC One Hour site, and, because of the widespread extent of the contamination and the number of people potentially impacted by the contaminated water, the dry cleaner was nominated and accepted for inclusion as a Superfund site in 1989.

A groundwater pump-and-treat system was installed on the site and placed into service in 1996 and continues to operate today. This system collects contaminated groundwater emanating from the area under and around the dry cleaner and treats it prior to discharge to a surface water body. It is scheduled to be in operation until groundwater cleanup goals are achieved, possibly by 2015. Contaminated soil containing residual amounts of perc is being addressed through a soil vapor extraction (SVE) system, which became operational in mid-1998. The SVE system is scheduled to function for at least another 10 years, until it has removed enough perc to allow soil to meet cleanup criteria. Investigation and remedial costs to date have been in excess of \$5 million.

### ALTERNATIVES TO PERC (PCE)

The ABC One Hour example is far from unique, and EPA estimates that there are thousands of dry cleaners around the United States that have released perc into the soil or groundwater. Many of these cleanups are being funded through private party insurance claims, while the costs of others are being borne by federal and state taxpayers. Fortunately, the dry cleaning industry is slowly moving away from perc to other cleaning solutions. These include the following.

#### Wet Cleaning

This is a system that uses biodegradable soap and water in combination with computer-controlled dryers and stretching machines to ensure that the fabric retains its natural size and shape. Wet cleaning is reportedly an acceptable alternative for almost all garments labeled "dry clean only," including leather, suede, and silk.

#### Silicone

This process uses siloxane, a combination of silicon, oxygen, and alkane known as decamethyl-cyclopentasiloxane, or D5, as the cleaning solvent. D5 also has a long, safe history of use as a component of cosmetics

and other personal hygiene products such as deodorants and shampoos, among others. The end products of a silicone-based dry cleaning process are sand, water, and carbon dioxide.

#### CO<sub>2</sub>

First developed commercially in the late 1990s, pressurized, liquid CO<sub>2</sub> combined with a surfactant (soap) is used as the dry cleaning solvent. At the end of the cleaning cycle, the CO<sub>2</sub> is recycled, and, if a release occurs, the CO<sub>2</sub> liquid quickly changes, or sublimates, to a common atmospheric gas and is not able to contaminate soil or groundwater. An added advantage is that CO<sub>2</sub> can be formulated without the use of petroleum products.

#### Alternative Petroleum Solvents

These substitute perc with different hydrocarbon solvents (e.g., Exxon D-2000 or Chevron-Phillips Eco-Solv), which are more biodegradable and less likely to contaminate soil and groundwater.

Each of these perc alternatives has its advantages and disadvantages, and all require expensive upgrades to machinery and equipment, in the range of \$100,000 for most operations. This type of capital investment may be beyond the reach of the majority of small dry cleaning operations that operate on thin profit margins in heavily competitive settings. More importantly, consumers will need to adjust their dry cleaning attitudes, as the use of perc alternatives will be more expensive and may not leave clothes as clean as many of us have come to expect.

1992 to 1996 and 36 million pounds (16 million kg) from 1998 to 2000.

### ENVIRONMENTAL RELEASE AND FATE

PCE is mainly released to the environment by evaporation into the air and especially from point sources such as dry cleaners and factories. In the atmosphere, PCE is primarily in the gas phase, where it degrades through photooxidation reactions. The half-life of this process may be as long as two months, allowing it to disperse over broad areas. It may be washed back to the surface through precipitation during this time. PCE released to soil mainly evaporates into the atmosphere. That which penetrates the soil slightly adsorbs to sand and clay particles, resulting in low to moderate mobility. It slowly leaches into the groundwater system and continues to sink into deeper supplies because it is denser than water (as a DNAPL). It appears that PCE undergoes slow biodegradation under anaerobic conditions in 21–150 days. If PCE is released to surface water, most evaporates into the atmosphere. The rest does not biodegrade or adhere to sediments, and hydrolyzation is extremely slow. It is no wonder that PCE is such a common contaminant in groundwater systems, even public supplies that serve large populations. A recent survey found PCE in 38 percent of surface water nationwide.

From 1987 to 1993, during the EPA Toxic Chemical Release Inventory, more than 1 million pounds (0.45 million kg) of PCE was reported as released to the natural environment from industrial sources alone. By far, the state with the largest amount of release was Louisiana, with far lesser amounts from South Carolina, New Hampshire, North Carolina, Illinois, Texas, Ohio, Indiana, Colorado, and Iowa, primarily from the chemical industry, various textiles, and leather products. Total annual PCE releases to the environment (industrial and commercial) decreased from 37.7 million pounds (17 million kg) in 1988 to 3.7 million pounds (1.7 million kg) in 1999, an impressive 10-fold drop.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects from PCE exposure. PCE has been used as an anesthetic, so the first effects are generally on the central nervous system; they include sleepiness, loss of coordination, dizziness, headache, and finally unconsciousness. More serious effects include eye and upper respiratory irritation, kidney and liver malfunction, and even death at a high enough dose. Long-term chronic exposure may produce head-

aches, abdominal discomfort, nausea, constipation, cirrhosis of the liver, hepatitis, nephritis, cardiac arrhythmia, increased spontaneous abortions, menstrual disorders, decreased fertility, and general kidney damage in humans. Animal studies mainly show damage to the liver, kidney, and central nervous system, as well as reproductive effects. The current classification for PCE is in group C-B2, as a possible human carcinogen to probable human carcinogen. Animal studies show a fairly strong link to increased risk of liver and kidney cancer and leukemia. Epidemiological studies on humans link PCE to cancers of the lungs, liver, skin, colon, cervix, larynx, urinary bladder, esophagus, and lymph glands. The problem is that the studies were done on people in the dry cleaning industry, and PCE is not the only potentially dangerous compound that the workers were exposed to on a regular basis. The connection is, therefore, inconclusive with the current information.

### REGULATIONS ON HUMAN EXPOSURE

Federal agencies have regulated the amount of public exposure to PCE. The EPA limits PCE in drinking water to five parts per billion (ppb) or less under the Safe Drinking Water Act. They further require that any release of 100 pounds (45.5 kg) or more be reported to the National Response Center. The Occupational Safety and Health Administration (OSHA) limits exposure of workers to 100 parts per million (ppm) (PEL) over an eight-hour-day, 40-hour workweek and a peak exposure of 300 ppm for a maximum of five minutes. The National Institute of Occupational Safety and Health (NIOSH) has set a designation of immediately dangerous to life and health (IDLH) for any exposure of 150 ppm or more. In their National Occupational Hazard Survey of 1972–74, NIOSH estimated that 1.6 million workers were exposed to PCE. In their National Occupational Exposure Survey of 1981–83, the number dropped to 566,000, and a 1994 industry survey further reduced the number to 450,000 workers.

**PCP (pentachlorophenol)** Pentachlorophenol is not the PCP that is used as an illegal drug; rather, it is a deadly pesticide. PCP was widely used in wood preservation and as one of the most common pesticides, but it has an odd environmental history. It commonly contains small amounts of dioxin, hexachlorobenzene (HCB), and furan even at technical grade. Early health problems associated with PCP were attributed to these other very dangerous substances. It took years of study to show that the PCP was also dangerous. As a result, PCP was listed as a restricted use pesticide (RUP) for most applications and banned from sale to the general public in 1984. After the restrictions, its use was greatly reduced both domestically and internationally, and it was banned altogether in several countries. PCP is also known as Penchlorol, Dowicide 7, Permasan, Fungifen, Grundier arbezol, Lauxtol, Liroprem, Chlon, Dura Treet II, Santophen 20, Woodtreat, Penta Ready, Penta WR, Forpen-50, Ontrack WE Herbicide, Ortho Triox, Osmose WPC, Watershed WP, and Weed and Brush KillerH. PCP has been identified in 313 of the first 1,585 U.S. Environmental Protection Agency (EPA)-designated Superfund sites (National Priorities List) in which it was tested. It ranks 45th of the 275 most dangerous pollutants on the 2007 CERCLA Priority List of Hazardous Substances. It is, therefore, regarded as one of the more hazardous pesticides, primarily by virtue of its toxicity, persistence, and extremely wide distribution.

## PROPERTIES, USE, AND PRODUCTION

PCP is a synthetic organochloride biocide in the category of semivolatile, chlorinated phenolic compounds. It occurs as colorless or tan to white needlelike crystals with a benzenelike smell. PCP is almost always mixed with other organic compounds. Even at technical grade, it contains 4–12 percent other chlorinated phenols and tetra-, hexa-, and octochlorodibenzo-p-dioxins (dioxin), polychlorinated dibenzofurans (furan), and chlorobenzenes (benzene), among other compounds. PCP has been available in blocks, flakes, granules, liquid concentrates, wettable powders, or ready-to-use petroleum solutions. PCP is primarily used as an insecticide (especially for termites), a fungicide, an herbicide, a molluscicide, a mossicide, an algicide, a disinfectant, a biocide in industrial water systems, and an ingredient in antifouling paint. It is primarily used as an industrial wood preservative for utility poles, cross arms, fence posts, railroad ties, and wharf pilings, as well as consumer products such as boats and log homes. Other uses include as a seed treating agent for beans; as a leather and textile treatment; in paper coatings, latex paint, food can seals, cooling tower additive, and food storage containers; and as a preservative for glues, starches, and photographic papers. About 10 percent of PCP is used to produce Na-PCP.

PCP was introduced as a wood preservative in 1936, and, by 1947, nearly 3,520 tons (3,200 metric tons) was used in the United States alone. By 1977, production was as much as 50 million pounds (22.7 million kg) per year but soon began to decline because of the health concerns and impending restrictions. In 1983, production was still at 45 million pounds (20.5 million kg), to 35 million pounds (15.9 million kg) in 1985, the year after the 1984 restrictions. By 2002, domestic production had dropped to 11 million pounds (5 million kg), with much of it exported.

## ENVIRONMENTAL RELEASE AND FATE

PCP is most commonly released to soil and air as a nonpoint pollutant, as are most pesticides. Through spills and leaks during manufacturing, transport, and storage, or from improper disposal, PCP may also be a point source pollutant. If released into the soil, PCP tends to bind to soil and sediment particles as a function of higher oxidation and lower pH and has low mobility. In this case, the PCP is removed primarily by biodegradation under anaerobic conditions, with a removal half-life of weeks to months (average 45 days) after a two- to three-week period

of microbial acclimation to it. Under certain conditions, however, it may remain as much as five years. If the soil is reduced and basic, PCP may be moderately mobile and leach into the groundwater system. It has been found in water from wells in California, Oregon, and Minnesota that were not near waste sites. The rate of degradation is concentration dependent by anaerobic microbial activity, averaging 38 days for three parts per million (ppm) and 57 days for 5 ppm. If released to surface water, PCP mainly binds to suspended particles and settles into the sediment. Some biodegradation and photodegradation happen at the surface and may be quick (hours to days) but account for very little of the release. That which remains in the sediment degrades very slowly and as a function of concentration, similarly to degradation in groundwater. PCP can evaporate from surfaces of treated wood. In air, PCP is degraded by reaction with photochemically produced hydroxyl radicals and by photolysis.

PCP also has a strong effect on ecological systems. Although it is slightly to nearly nontoxic to birds, PCP is highly to very highly toxic to most species of fish. It is also toxic to mammals. Farm animals that licked PCP-treated wood became sick and, in some cases, died. PCP is also toxic to strongly toxic to plants and can be taken up and accumulated in some plant species. PCP is very toxic to insects, fungus, moss, and aquatic invertebrates.

In the EPA 1987–93 Toxic Chemical Release Inventory, reported industrial releases of PCP totaled 98,480 pounds (44,764 kg) to land and water, 80 percent of which was to land, with a total release of 991,211 pounds (450,550 kg). The top state by far was Nevada, followed distantly by Oregon, Washington, Arizona, and Georgia, primarily from the explosives, wood preserving, and chemical industries. In 1998, the total release was 271,495 pounds (123,406 kg), primarily in Idaho, followed distantly by Alabama, with minor amounts in Oregon, Washington, and Texas. By the time of the 2005 Toxics Release Inventory, only 16,933 pounds (7,697 kg) of PCP was reported released by industry that year.

### HEALTH EFFECTS FROM EXPOSURE

PCP is considered to be moderately to highly toxic. Exposure can have many sources in everyday life, including by eating fruits and vegetables. Once in the body, it can be very persistent with an elimination half-life of as long as 20 days. This persistence means that short-term exposure can produce long-term effects. Short-term exposure to PCP in even small amounts by inhalation, ingestion, and even

dermal contact can result in poisoning. Symptoms may include dizziness, mental confusion, restlessness, sweating, hyperthermia with high fever; eye, nose, and throat irritation; difficulty in breathing; muscle weakness, spasms, and tremors; chest and abdominal pain; and, if the dose is high enough, death by respiratory failure. Long-term exposure quickly leads to liver, kidney, blood (anemia), and nervous system damage, as well as skin rashes including chloracne; and to weight loss, permanent vision damage, fatigue, weakness, bronchitis, and circulatory obstruction, including heart failure, and excessive sweating. The chloracne may be the result of dioxin poisoning. PCP may also damage developing fetuses, increasing the risk of miscarriages, low birth weight, and birth defects including skeletal abnormalities. Sudden infant death syndrome has also been reported in some cases.

PCP is considered to be possibly carcinogenic to humans (group 2B) by the International Agency for Research on Cancer (IARC) and to be a probable human carcinogen (group B2) by the EPA. PCP has been linked to increased incidence of Hodgkin's disease, acute leukemia, and soft tissue cancer of the lip, mouth, and pharynx, among other sites in humans, and cancers of the liver, adrenal gland, and spleen in laboratory animals. Although PCP products were long known to be associated with increased cancer, it was not clear whether the culprit was an impurity such as dioxin, which is a known carcinogen, or whether PCP itself was the cause.

### REGULATIONS ON HUMAN EXPOSURE

Federal agencies regulate worker and general exposure to PCP as the result of these health risks. The EPA limits the amount of PCP in drinking water to one part per billion (ppb) under the Safe Drinking Water Act and requires the reporting of any environmental release of one pound (0.45 kg) or more to the National Response Center. The Occupational Safety and Health Administration (OSHA) restricts the amount of PCP in workplace air (PEL) to 0.5 mg per cubic meter for an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) has set the same general exposure limit (REL) as OSHA and a designation of immediately dangerous to life and health (IDLH) for any exposure of 2.5 mg of PCP per cubic meter of workplace air. PCP was severely restricted for most applications in Europe by the early 1980s and in the United States by 1984. It is completely banned in Germany, Finland, and Sweden, among other countries.

#### **Pennsylvania coal mine fires Centralia, Pennsylvania (May 1962–present) Air Pollution**

There are stories that as the result of a lot of garbage after a May Day or Memorial Day parade in Centralia, Pennsylvania, municipal workers decided to burn the refuse in the newly opened town dump in an abandoned coal strip mine. Others say that it was the act of a careless trash hauler who dumped smoldering refuse in the town dump. Whether an event was the reason to start the fire or garbage was just piling up too fast in the new dump is unclear. What is clear is that the fire spread into a mine shaft off the strip-mined area and ignited a coal seam underground. With enough air remaining in the maze of old mine shafts that exist in this coal mining area, the fire was able to spread unchecked underground. This simple act of burning a pile of garbage would initiate an incident that would doom the town of Centralia and threaten all of the surrounding towns. The fire still burns today, and now it can never be extinguished.

#### **THE TOWN OF CENTRALIA**

Centralia was in Columbia County, Pennsylvania, in the heart of coal country. The first record of a settlement in Centralia, then known as Centreville, was in 1841, but the town was not incorporated as Centralia borough until 1866. The whole reason for the existence of the settlement was to mine coal. In 1854, Alexander Rea, a civil engineer for the Locust Mountain Coal and Iron Company, developed the plan for the physical layout of the town. Activists of the Molly Maguires, an Irish underground miner terrorist organization who frequented the area during the 1860s and 1870s, murdered Rea in 1868. Three men were hanged in 1878 for the crime.

Perhaps this tragic beginning doomed the town, but during most of its history no one would have suspected that it was doomed, because the town flourished. Employment was high thanks to the coal mining industry, which kept it relatively prosperous. A major rail line served the town, and there was an active downtown area with a variety of businesses and shops. The population remained above 2,000 residents with 500–600 just outside of town throughout its history. The peak population was 2,761 immediately before the fire began. This would change quickly.

#### **THE UNDERGROUND FIRE**

The sequence of events that would lead to the demise of Centralia began in early 1962, when the town council decided to abandon the old and overfilled town landfill for a new location in an old strip mine. The mine pit had numerous holes in it where it intersected with old underground mines and where seams were followed but abandoned. By Pennsylvania law, these openings of all kinds had to be sealed before the pit could be used as a landfill to prevent surface leakage, including fires, into the underground system. The town performed the required sealing and was issued a permit by the state. They began using the pit as a landfill as soon as it was open.

The fateful incident of burning the trash took place at the end of May 1962. It is reported to have been conducted by volunteer firemen hired by the town, but municipal workers were probably involved as well. The fire, referred to as "the Incident" by locals, was extinguished, or so they thought, after it was done. The fire flared up a few days later, and the fire department extinguished it again. It was at this point that the one unsealed hole in the pit floor was discovered beneath the burning garbage. This one hole was the gateway to a century's worth of interconnected mine shafts, and the fire exploited it.

Smoke from an underground coal mine fire vents near Centralia, Pennsylvania. (© Leif Skoogfors/CORBIS)

The fire quickly spread through the abandoned tunnels, burning both coal dust and debris and the remaining coal in the walls. There was and is not enough oxygen in the mine for a complete burn of the coal. As a result, the main pollutant being emitted is carbon monoxide. Other pollutants also result from partial burning but rarely are emitted at the surface. These pollutants include particulate, polycyclic aromatic hydrocarbons (PAHs), benzene, and others. Residents began complaining of symptoms of carbon monoxide poisoning soon after the fire began. There was a rash of unexplained headaches, nausea, and flulike symptoms that would strike entire families for extended periods. There are reports that the Pennsylvania Department of Environmental Resources began drilling monitoring wells to observe the progress of the fire as early as July 1962.

Through the years, the fire spread, and its evidence became apparent. By May 1969, the first three families were relocated from Centralia because their homes were no longer safe. In 1979, a gas station owner noticed that the gasoline in his underground tanks seemed warm. He lowered a thermometer into the tank to find that the gasoline was 172°F (77.8°C). In 1981, the situation was

called to national attention when a sinkhole suddenly opened under the feet of a 12-year-old boy. The hole was four feet (1.2 m) wide and 150 feet (45 m) deep; the fall into it would have killed him, but he grabbed some roots at the last minute. Luckily, his older cousin was with him and pulled him out of the hole. Many other such sinkholes began opening in other parts of the town as well.

### CONFRONTING THE BLAZE

There were many efforts over the years to confront the fire, but none of them was particularly concerted or effective. The first attempt to stop the spread was in 1969, seven years after it had begun. Trenches and clay caps were installed around the area where the fire started, but the project was not well planned or executed and ultimately never completed. The chance for success was poor anyway because the fire had spread too far by then.

By the time the situation had attracted public attention in 1981, some \$7 million had been spent to extinguish the fire. The mines had been flushed with water and fly ash, excavated to remove the burning material, trenched and backfilled, and drilled numerous times to delineate the extent of the fire. In

response to the public attention, in 1983, the state proposed an ambitious plan to dig a trench 500 feet (154 m) deep around the town to contain the fire and to condemn and purchase all of the homes and businesses. The total cost of the plan was \$660 million, and there was no guarantee that it would work. In the end, the U.S. Congress allocated \$42 million to buy out the residents and decided to let the fire burn itself out. They hoped that it would not spread.

The process of purchasing the homes and businesses began immediately, and the last purchase of the plan was for 26 homes just west of Centralia in 1991. In the following year, the state of Pennsylvania claimed eminent domain and condemned all remaining homes. The main thoroughfare in town, Route 61, began to crack and melt in several places, and after several unsuccessful attempts at repair, it was closed in the mid-1990s and detoured around the area. In 2002, the U.S. Postal Service revoked the borough's zip code.

Today, the fire is estimated to underlie an area of 400 acres (162 ha) and to be growing daily. There are several warning signs posted around the area and several metal steam vents. Unhealthy smoke and gas escape from surface vents, both constructed vents and holes in the ground, in various locations, and there are sinkholes in several spots. There are no plans to extinguish the fire, and it may take as much as 250 years to burn out on its own.

### COAL MINE FIRES: A GLOBAL PROBLEM

The upheaval of the entire population of the town of Centralia was an emotional and economic crisis for the residents. This, however, is not the only coal mine fire in the United States or even in Pennsylvania. The towns of Carbondale, Laurel Run, and Vanderbilt, Pennsylvania, may come to the same end as Centralia. There are literally hundreds of coal mine fires in American coal mines, many of which threaten to produce the same results as in Centralia in other communities. They are already degrading the air quality in these communities to unhealthy levels in some cases. The United States is not the only country with coal mine fires; they are an international problem. Australia has an underground coal fire that is estimated to have been burning for 6,000 years, the oldest of its kind. Indonesia is beset with extensive coal mine fires that foul the air to the point where resulting respiratory ailments have become epidemic in some areas. The worst case of coal mine fires is in China, where some 20–200 million tons (18–180 million metric tons) of coal is consumed each year. It is

estimated that these fires alone make up 1 percent of the global fossil fuel consumption and thereby contribute to carbon dioxide emissions and global warming.

**perchlorate** One of the most controversial and vigorous of the current environmental debates centers around the compound perchlorate. Even though there are no regulations or even definitive health studies demonstrating a danger to the environment or public health, high-profile politicians debate the perchlorate controversy in the U.S. Congress and in the press. Entire communities have filed lawsuits against manufacturers and consumers, claiming crises in public health as a result of exposure to perchlorate. Clearly, with no regulations or even reliable health studies, this debate is relatively new. This is surprising, considering that perchlorate has been used extensively since the 1950s. The catalyst for the debate is the discovery that more than 20 million Americans are regularly exposed to perchlorate in their drinking water. Couple this wide distribution and exposure with a theoretical possibility of health problems and the controversy was born.

## PROPERTIES, USE, AND PRODUCTION

The term *perchlorate* really just refers to the ion  $\text{ClO}_4^-$ . What is meant by the term is perchlorate salt, which is produced by the reaction of perchloric acid with some other compound. There are many perchlorate salts including ammonium perchlorate ( $\text{NH}_4\text{ClO}_4$ ), cesium perchlorate ( $\text{CsClO}_4$ ), lithium perchlorate ( $\text{LiClO}_4$ ), magnesium perchlorate ( $\text{Mg}(\text{ClO}_4)_2$ ), potassium perchlorate ( $\text{KClO}_4$ ), rubidium perchlorate ( $\text{RbClO}_4$ ), silver perchlorate ( $\text{AgClO}_4$ ), and sodium perchlorate ( $\text{NaClO}_4$ ), among others. They can be synthesized or occur naturally in some arid areas. Of these salts, the compound of greatest interest is ammonium perchlorate because it is the primary component of solid rocket and missile fuels and propellants, among other fuels. It first went into production in the 1940s for purely military purposes. In addition to rockets, it was used in explosives, mortars, grenades, and flares. It is estimated that more than 90 percent of all ammonium perchlorate produced was either used in military applications or by the aerospace industry (including fuel for the Space Shuttle). The remaining 10 percent was used in conjunction with other perchlorates (primarily potassium and sodium) in pyrotechnics and fireworks, blasting agents, matches, lubricating oil, nuclear reactors, electronic tubes, paints and enamels, tanning and leather finishing, air bags for automobiles, and certain types of fertilizers. Perchlorate occurs naturally in some potassium nitrate fertilizers from Chile, which were extensively produced and imported to the United States in the early 20th century. Lithium perchlorate is used for oxygen candles that produce lifesaving oxygen for miners and other workers during emergencies. Potassium perchlorate is used in protective breathing devices in the U.S. Navy and U.S. Air National Guard.

## ENVIRONMENTAL RELEASE AND FATE

Perchlorate is primarily a point source pollutant from military installations (air force, navy, and some army), disposal sites, and manufacturing plants. It is also a nonpoint source pollutant from fertilizers and fallout from pyrotechnics and aerospace and military applications. As a result of military weapons testing and improper dumping of perchlorate in Arizona, California, and Nevada, most of the drinking water in those states is tainted including the water in the Colorado River, which supplies some 20 million people. It is not, however, restricted to these states. Perchlorate has been found in water from 25 states, and it is expected that locations in 43 states will be identified. It is known to have been produced,

stored, or used at more than 150 sites in 36 states, many of which have yet to be tested. There remain at least 63 military sites in 32 states where rockets, missiles, and munitions were used where testing for perchlorates has yet to be done.

When perchlorate is released into the soil, it adheres only weakly to soil particles. For this reason and because it is highly soluble in water, it is highly mobile in soil and able to be readily leached into the groundwater system. Once in groundwater or surface water, it is relatively inert, rarely undergoing chemical reactions that might remove it. It also tends to stay in solution. For these reasons, it is very persistent in water, able to remain a threat for extended periods. It is even able to remain in solution through uptake into plants. It has been detected in lettuce, cow's milk, various vegetables, and human breast milk. Preliminary bioaccumulation factors for perchlorate in leafy vegetables are as much as 65 times ambient water levels, thus increasing the risk.

## HEALTH EFFECTS FROM EXPOSURE

Strangely, potassium perchlorate was used in great quantity in the 1950s and 1960s to treat hyperthyroidism resulting from Graves' disease, and it is still used to determine thyroid hormone production in some clinical settings. It is strange because it is the thyroid that is most at risk from perchlorate exposure. Perchlorate interferes with iodine uptake into the thyroid gland, and iodine is an essential component of hormones from the thyroid; thus, its function can be disrupted. The thyroid gland regulates metabolism in adults and children alike. In children, however, it is also important in development, which can be delayed by thyroid malfunction. The real danger is to pregnant mothers, because thyroid malfunction can impact the fetus, causing behavioral problems; increased mental retardation; loss of hearing and speech; delayed development, including deficits in motor skills; and decreased learning capacity, including significantly reduced IQ in offspring. There is also evidence that perchlorate exposure may increase the risk of thyroid cancer. There is a possibility that perchlorate works synergistically with other compounds such as nitrates to worsen the health effects.

## REGULATIONS ON HUMAN EXPOSURE

At this point, there are no regulations for environmental exposure of perchlorate, but there is an enormous amount of activity in the federal regulatory agencies, and regulations were expected by 2008.

To date, the U.S. Environmental Protection Agency (EPA) has established an official reference dose of 0.0007 mg of perchlorate per kilogram of body weight per day, though the National Research Council considers it to be too stringent. With this reference dose, the limit of perchlorate in drinking water would be set at 25 parts per billion (ppb) under the Safe Drinking Water Act. California, however, one of the most strongly impacted states, considers this level too lax and has an advisory level of 2–6 ppb. Recently, the EPA has been considering a range of 4–18 ppb in a draft version.

**pesticides** Pesticides have a reputation both as a boon and as a scourge in modern society. The best example of this conflicting reputation is dichlorodiphenyltrichloroethane (DDT), the most notorious of the pesticides. Although DDT was invented in 1874, its properties as a pesticide were not discovered until 1939. This discovery was heralded as one of the greatest in the history of modern civilization. In recognition of this work, Paul Muller, the discoverer of these properties, was later awarded the Nobel Prize. In contrast, in her book *Silent Spring*, Rachel Carson specifically targeted DDT as the most

dangerous chemical in the environment. Her efforts sparked the American environmental movement. As a result, the U.S. Environmental Protection Agency (EPA) was created, and one of its early and most heralded efforts was to ban DDT.

Pesticides can be credited for a large part of the vast success of the human race in the 19th and 20th centuries. DDT alone essentially banished typhus and malaria from Europe and North America and even started the fight in other areas. The pesticides control disease-carrying insects and vermin, thereby limiting human contact. Estimates of the number of people whose lives have been saved by this indirect effect of pesticides are in the hundreds of millions. In addition, pesticides control the insects, plants, vermin, and other threats that consume and destroy the food supplies on which humans depend. The ability of modern civilization to feed the burgeoning human population of the past two centuries is certainly to a large degree the result of the effectiveness of pesticides. Pesticides protect the seeds, plants, and produce throughout the growing cycle and greatly enhance the yields. Agricultural efficiency has increased around the world as a result of pesticides, in some cases on the scale of orders of magnitude.

To achieve this efficiency, huge amounts of pesticides must be manufactured and applied to crops. Some classification systems consider the chemicals used in water purification to be pesticides. If so, they constitute about half of all pesticides used. For this discussion, only conventional pesticides are considered in detail. These are the pesticides that are applied directly to food, seeds, or living plants (and/or their surroundings) to control specific target organisms. This use constitutes about 23.3 percent of all pesticide application in the United States, or roughly 1.24 billion pounds (563 million kg) per year. Considering that global consumption of conventional pesticides is about 5.7 billion pounds (2.6 million metric tons), the U.S. part is about 20 percent.

If pesticide application had been handled judiciously, the environmental movement might have been longer in getting established. The problem was that they were applied almost indiscriminantly in virtually all agricultural areas. They began not only to control the pests but also to affect desirable species negatively. They entered soils, water, and air and bioaccumulated and biomagnified in nontarget species. By the 1960s, they were regularly being found in foods to which they had not been applied. There was an alarming increase in pesticide residues in human mother's milk, to the point at which it was recommended that mothers in some areas avoid

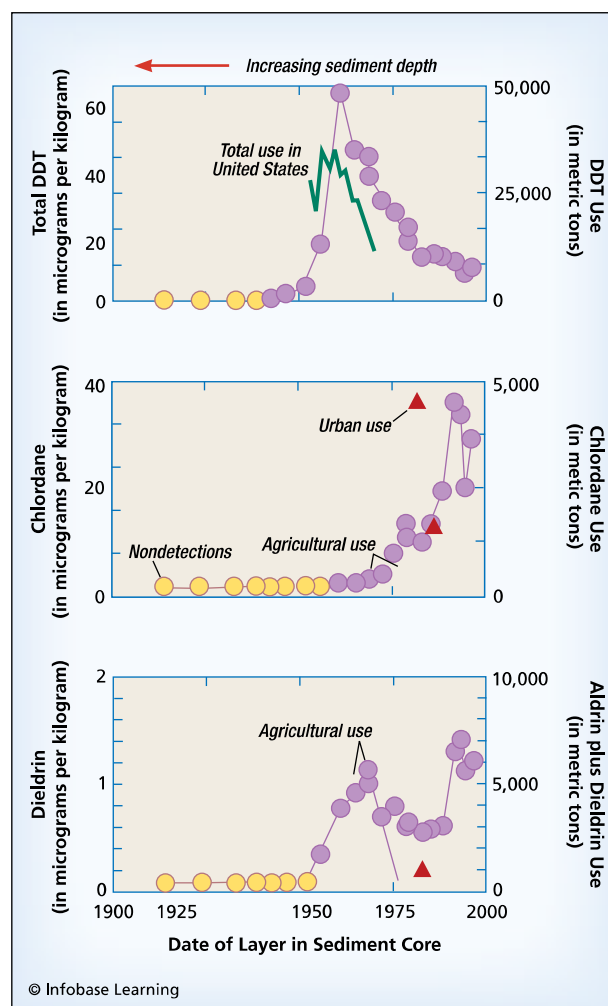

nursing. Pesticides were carried so far into the atmosphere that they were discovered in glacial ice. It is to the credit of the work of the environmentalists that governmental efforts to reduce pesticides through the 1970s and 1980s significantly reduced pesticide residues in milk, to the point where there is little danger from them. Recently, the problems with pesticides have shifted to the severe damage they cause to beneficial species. These are significant enough to undermine the beneficial aspects of the pesticide in some cases.

### CLASSIFICATION OF PESTICIDES

There are numerous classification systems for pesticides. The main system of classification is based upon the pest to be controlled. The primary type of pesticide is an insecticide, in which the primary targets are insects. Insecticides are used in agricultural applications, as large-scale preventative measures, and in individual applications around homes. In agricultural applications, they can be applied to seeds, to soil, or directly to plants either by spraying or from airplanes through crop dusting. Large-scale preventative applications usually involve spraying and are usually done to control destructive or potentially disease-bearing insects such as mosquitoes. Household insecticides are typically used to control insects that are health threats such as wasps and cockroaches or threats to property such as termites and carpenter ants. Household use of insecticides must be carefully monitored because of the potential threat of accidental poisoning.

Herbicides (including algicides and fungicides) are generally considered separately from pesticides in most classifications but are briefly included here because they are not always separated. Herbicides control the growth of unwanted vegetation with minimal damage to the surrounding plants and animals. They can be used in agricultural applications, especially with regard to ornamental plants, and household applications. In agriculture, they control the growth of plants that could compete with the crops for resources. The most widespread use of herbicide is on lawns and around ornamental plants at private residences. This application spreads herbicide throughout most suburban areas in an effort to remove weeds that might compete with grass. Herbicides can also be sprayed on undergrowth along roadsides, on plants that threaten health and safety such as poison ivy, and in lakes and ponds to control weeds.

Other pesticides include fungicides to control fungal growth on seeds, crops, and ornamental plants. Rodenticides are used to control mouse and rat pop-

**Graphs of the concentrations of three common pesticides (left side) from a sediment core taken from White Rock Lake, Texas, and total use (right side) versus depth/time before present in years from 1900 to 2000. It shows continued accumulation of these pesticides decades after their last use. DDT and dieldrin were banned in 1972 and 1974, respectively, and most uses of chlordane were stopped in 1983.**

ulations. Avaricides are used to control unwanted bird populations. These and other specialized pesticides can be used in agricultural and private home applications, but their use is volumetrically minor relative to that of insecticides and herbicides.

There are also chemical classifications of pesticides. They can be inorganic, organic, and biological agents. Inorganic pesticides are compounds that contain lead, mercury, copper, arsenic, or the like. They may be highly toxic and are virtually indestructible, remaining active indefinitely. They can be used as seed coatings but are commonly used on wood and in other nonedible applications. Biological agents are living organisms or toxins derived from them that can be used in place of conven-

tional pesticides. They may be insects or bacteria that remove unwanted species. They are commonly used in organic gardening.

Organic pesticides are generally divided into the following four main types:

1. Organophosphorus: most common are parathion, malathion, and dichlorvos.
2. Carbamate: most common are carbaryl (a.k.a. Sevin), aldicarb, and carbofuran.
3. Organochlorine: most common are chlordane, Toxaphene, heptachlor, DDT, methoxychlor, Endrin, aldrin, dieldrin, and lindane.
4. Botanical and others: typical examples are nicotine (from tobacco), pyrethrum (from chrysanthemums), and rotenone (root extract).

All of these types have different properties and characteristics and are designed to control specific species under a specific set of conditions. These properties include toxicity, selectivity, chemical stability, persistence in the environment, mobility, and physical form. Organophosphorus pesticides are generally extremely toxic (10–100 times more powerful than all others) but generally break down very quickly in the natural environment. They attack the nervous system by inhibiting cholinesterase, causing rapid death in insects, birds, mammals, fish, and humans alike. Their development formed the precursor to the highly toxic nerve gas weaponry during World War II. Carbamates can be moderately to very highly toxic but are only moderately persistent at best and are relatively mobile. Many compounds share the characteristics of organophosphates in terms of action and toxicity, but others are less potent and more persistent. Organochlorine pesticides are highly toxic and highly persistent in the environment, remaining for several decades, in some cases. Several have been banned from sale and usage because they were determined to be a threat to the environment or human health. Botanicals, or natural organic pesticides, are most commonly used by organic gardeners and environmentalists because they are the least damaging to the environment. They are also the least effective of the organic pesticides.

Fumigants are also organic pesticides. They are small-molecule compounds that evaporate easily and then penetrate the pores of a variety of materials, thus protecting their interiors. Examples of fumigants include carbon tetrachloride, carbon disulfide, ethylene dichloride, and methylene bromide. They

are moderately to highly toxic, and, as gases, they are very dangerous to work with; as a result, many have been restricted or banned.

## PESTICIDES IN THE ENVIRONMENT

Pesticides were designed to kill living organisms. Aside from the natural pesticides such as many of the botanicals, pesticides are very harsh on the environment. The degree to which they damage the environment depends mainly upon toxicity and persistence, but several other factors related to their mobility control the degree to which they will be spread from the point of application. The farther the pesticide is spread from the application site, the more likely it is to affect the environment.

Upon release, pesticides may either evaporate into the air as a vapor or enter the soil/water system as a solid or liquid depending upon the vapor pressure. That which enters the air may break down by photodegradation through exposure to sunlight or interaction with air pollutants. If it does not break down, it may settle to the ground as fallout, either directly or by attaching itself to dust particles, or it may be washed out by precipitation. Pesticides may travel long distances in this way to areas that should be remote from pesticides such as glacial ice in Antarctica or the sands of the Sahara.

Resistance to chemical breakdown is persistence. It is measured in removal half-life, which is the time required to remove half of the mass of the pesticide from the environment either by physical removal or by chemical/biological breakdown. Chemical breakdown occurs through the chemical reaction of the pesticide with air, soil, or water to produce less toxic by-products. Biological removal is typically accomplished through microbial activity either in the presence of oxygen (aerobic) or without it (anaerobic). These microbes dissociate the pesticide to use the carbon atoms as nutrients. Persistent pesticides are usually toxic to the soil and water microbes. If the half-life of the pesticide is 30 days or less, it is considered to be of low persistence. Examples of low-persistence pesticides are aldicarb, malathion, and methyl parathion. If the half-life of the pesticide is 30–100 days, it is considered to be of moderate-persistence. Examples of moderate-persistence pesticides include aldrin, atrazine, carbofuran, diazinon, endrin, heptachlor, parathion, and phorate. High-persistence pesticides have half-lives greater than 100 days and include such compounds as trichloroethane (TCA), chlordane, paraquat, lindane, and DDT. More persistent pesticides can be spread farther from the point of application without breaking down.

Mobility of pesticides is another property that determines their impact on the environment. Once released into the soil, pesticides may adhere to soil particles in a process called adsorption. The degree to which the pesticide is adsorbed determines its mobility. Pesticides that are adsorbed to soil most commonly attach themselves to organic particles or clays. They are fixed and immobile. Pesticides that do not attach to these particles are considered mobile and can leach or percolate into the groundwater system. There they can spread long distances and affect human activities, as well as the natural environment. Degree of solubility in water is the main factor in the degree of mobility of a pesticide. In sandy soils, even pesticides with a tendency toward immobility may be mobile and leach into the groundwater system with the mobile components. Another process that mobilizes immobile pesticides is erosion. Surface runoff can erode soil with pesticide adsorbed to it and carry it into the surface water system. There, it may be carried in suspension for great distances. Wind may perform the same function in arid regions.

The final major factor in the effect of pesticide on the environment is whether it is systemic or not. Some pesticides are absorbed through the root systems and distributed throughout the plant, whereas others are simply topical. Those that are taken up by the plant are considered systemic. Once they are sprayed on soil, residues of systemic pesticides may be found in the plants in those soils for many years after the application has ceased. They continue to absorb the pesticide from the soil preferentially. Nonsystemic pesticides are only effective when they are on the surface of the plant and do not participate in the system after they have been washed off or harvested.

### REGULATION OF PESTICIDES

To address the moderate to extreme toxicity of pesticides, their distribution, application, and human and environmental exposure are highly controlled both by the U.S. local and federal governments and by international governments. In the United States, there are at least 14 federal acts regulating some part of the manufacture, registration, distribution, use, consumption, and disposal of pesticides. The primary act in this regulation is the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), which governs the national registration, distribution, sale, and use of pesticides. Environmental and human exposure is primarily regulated by the Clean Air and Water Act and the Safe Drinking Water Act. All of the statutes of these acts are enforced by the U.S. Environmental Protection Agency (EPA). Individual states may

choose to impose more stringent standards than the federal government to address some local concern or the will of its residents. California typically has the most stringent regulations in the United States.

For new pesticides put on the market, the EPA requires justification that there is economic need for it as well as evidence of its safety. They may require up to 70 individual tests on the new product, which can cost the company millions of dollars. These tests demonstrate safety to humans and the environment, and the fate of the pesticide once it enters the environment. If a pesticide is particularly dangerous, it is assigned a restricted use pesticide (RUP) status, which requires special handling by certified professionals. It typically takes six to nine years to move a new pesticide from laboratory to market including at least two to three years to gain EPA registration approval. The EPA began requiring these extensive data on pesticides in 1978. Since then, they have registered 130 new active ingredients in pesticides, with 10–15 new registrations per year.

Pesticides that were developed before the current stringent requirements have gone through a reregistration process under EPA. Old pesticides had to be tested and evaluated at nearly the same level as new pesticides. Reregistration turned into a massive process that was proceeding so slowly that in 1988 amendments were added to FIFRA requiring that the entire reregistration process be complete by 1997. During this review process, there were several actions that the EPA could take for particularly dangerous pesticides. A special review was called to modify or deny registration. The result of the special review was either cancellation of the pesticide or registration under different terms. If the pesticide posed an imminent threat to human health or the environment, its sale and use would be suspended during the special review process.

The EPA also sets maximal legal limits for pesticides on foods and in animal feed available for sale in the United States. This authority is granted to the EPA under section 408 and/or 409 of the Federal Food, Drug and Cosmetic Act (FDCA). Under this authority, the EPA has approved about 300 pesticides for food uses; about 200 of them are in common use.

### CURRENT PROBLEMS WITH PESTICIDES

There are three major problems with pesticides at this time: collateral damage to beneficial species, imports of food from countries with different regulations, and evolving immunities to effective pesticides. The ultimate driver of problems with pesticides is the overwhelming demand of the burgeon-

ing human population on resources of the Earth as well as perhaps some greed among food producers. The demand for food is so great that the efficiency of farmland is pressed to its limit in many areas. Efficiency not only means deriving the maximal yield from crops, which involves overuse of fertilizers, but also converting these crops into sales of market items. The loss of crops to pests in this frenzied economy is almost unacceptable. As a result, farmers tend to overuse pesticides as well. Further, the demand of homeowners and Americans in general for well-landscaped and insect-free communities and properties further adds to the problem of excess pesticides in the environment.

The problem of collateral damage to beneficial species has been projected as the downfall of human civilization by some. Not only do pesticides kill the target insects, they also kill many insects and other small organisms that form the base of the food chain. As their populations are reduced, their predators have less food and their population is reduced, as are the organisms that prey upon them. Considering that humans are at the top of the food chain, this sequence of events eventually leads to food shortages. This problem has been occurring relatively unchecked or marginally checked for decades. Even more dangerous is the damage to beneficial species on which we depend. Chief among these are the bees. The vast majority of the pollination of flowering plants, trees, and shrubs is accomplished by bees. The pollination is necessary for the growth of fruits and nuts. The bee populations steadily declined throughout the second half of the 20th century. The North American bee population began to go into crisis in 2004, when a strange syndrome called colony collapse disorder (CCD) caused the destruction of entire colonies. By 2007, North America lost one-third of the bee population in one year. CCD has been blamed on parasites and disease, as well as a new pesticide called imidacloprid. Even if the cause is a disease or parasite, it is possible that the declining health of bees over the years of pesticide exposure, as well as this new highly toxic pesticide, made them susceptible to it. In any event, the elimination of bees has been predicted to herald the destruction of mankind.

Concurrently with the loss of beneficial species, evolutionary adaptations have occurred in the target species that improve their resistance to common pesticides. Not only is there a decline in the insects that help humans, there is an increase in those that do not. Insects such as cockroaches, fleas, ticks, ants, and termites now resist poisoning in significant numbers. New pesticides are being developed in great haste to combat this problem, but they pose new threats to the beneficial species.

#### **Petrobras oil platform failure Brazil, offshore (March 15, 2001) Water Pollution**

Petrobras (or Petróleo Brasileiro S.A.) was founded in 1953 and operated as Brazil's state-owned oil exploration and production company. In 1997, outside investors were allowed to buy stock in the company, although slightly more than 50 percent is still owned by the Brazilian government. Headquartered in Rio de Janeiro, Petrobras produces and distributes more than 2 million barrels (84 million gallons [320 million L]) of oil and oil-related products every day from its own wells, refineries, and pipelines. It is one of the 500 largest companies in the world.

#### **BACKGROUND**

Well known for its technological skill in drilling and finding oil in deepwater settings where the seafloor is between 1,000 and 4,500 feet (300–1,500 m) below the surface, the company began operating the world's largest offshore oil production platform, *Petrobras Platform 36 (P-36)*, 80 miles (129.8 km) off the Brazilian coast in 2001. The platform was constructed in 1995 by Fincantieri, one of the oldest and largest oceangoing vessel building companies in Europe, at a cost of more than \$300 million. *Petrobras Platform 36 (P-36)* originally was designed as a semisubmersible drilling and exploration rig, equipped with pontoons and columns, which, when

flooded, allowed the rig to sink to a predetermined depth and drill a well. These types of rigs are usually attached to the ocean bottom with mooring chains. Others use a series of computer-controlled dynamic positioning propellers or thrusters mounted on each corner of the platform to keep the rig centered over the borehole. Readily available, usable under a variety of conditions, and inexpensive (compared to jack-up and other types of platforms), semisubmersible drilling rigs can operate in water depths ranging from 2,000 to 5,000 feet (609.6 to 1,524 m) and are able to be detached quickly and towed to the next location after a well is completed and placed into service.

Weighing more than 33,000 tons (30,000 metric tons), *P-36* was converted from a drilling platform to an oil production platform by a Canadian company hired by Petrobras. These platforms are very large structures, some having working surfaces of more than several thousand square feet, where all machinery and support facilities needed to produce oil are placed, including housing for workers, spare parts, pumps, and so forth. Platforms can either be attached to the seafloor with large cables or mooring lines or be floating structures, maintained in position by a series of computer-controlled impellers, or water-thrusting engines. Artificial islands, made of fill material dumped from a barge or pumped to a specific location, are even constructed over large oil fields to serve as production platforms. *P-36* was a floating platform that connected or manifolded numerous oil wells extending from the seafloor into a pipeline that connected to a land-based oil storage terminal in Brazil.

*P-36* was extracting oil from Late Cretaceous and Tertiary sandstones and carbonates deposited in the Roncador oil field of the Campos Basin. The first producing well in the Campos Basin was put online in 1977, and today there are almost 500 wells spread out across 40 known reservoirs. The Campos Basin produces more than 1 million barrels (42 million gallons, or 159 million L) of oil and 565 million cubic feet (16 million m<sup>3</sup>) of natural gas every day. Reserves have been estimated at more than 8.5 billion barrels of oil (357 billion gallons or 1,351 billion L). The basin covers an area of almost 12,000 square miles (31,000 km<sup>2</sup>) and was formed as sediments rich in organic matter washed into shallow surface water bodies present along the east coast of Brazil. As the climate became drier, large deposits of salt formed, effectively sealing the oil within the sandstones and carbonates. These host rocks were later fractured and broken, and the hydrocarbons migrated into the open, interconnected breaks and formed large reservoirs of oil and natural gas.

## ACCIDENT AND SPILL

By March 2001, *P-36* was floating 80 miles (130 km) off the coast and producing about 84,000 barrels (4.4 million gallons [16.6 million L]) of crude oil and 46 million cubic feet (1.3 million m<sup>3</sup>) of natural gas per day, about 5 percent of all the oil produced by Petrobras in Brazil. Early in the morning of March 15, three powerful explosions rocked one of the aft starboard (rear left) support columns of the *P-36* platform. Ten workers were killed outright, their bodies never recovered, and another later died of severe burns. The platform quickly developed a pronounced list or tilt, which allowed seawater to rush in and flood the fairlead boxes. These are devices inside the support column where cables are stored or spooled, and the leads are used either to guide or position rigging cables around a fixed object or to allow them to uncoil in such a manner as to be clear of obstructions. Once these boxes or storage containers filled with seawater, the platform's list increased to almost 20 percent. The 164 workers left alive after the explosions were evacuated, and Petrobras quickly began salvage efforts to try to save the platform.

Rescue teams work to prevent the oil company Petrobras's platform *P-36* from sinking in the Campos Basin offshore from Brazil, March 18, 2001. (AP Images)

Divers arrived and, over the next five days, pumped a mixture of nitrogen (more than 4,000 tons [3,628 metric tons]) and compressed air into the damaged column to force out the seawater and stabilize the platform, thus preventing the list from becoming worse. Unfortunately, the column had been extensively torn open in the explosion, and, when the weather changed on March 20 and strong winds and heavy seas began to buffet the structure, salvage attempts were abandoned. Within a few minutes after divers cleared the 40-story-tall platform, *P-36* quietly slipped below the surface and sank in 4,000 feet (1,200 m) of water. Onboard was an estimated 400,000 gallons (1.5 million L) of oil.

The oil being pumped from the Campos Basin was fairly “heavy” crude, with an American Petroleum Industry (API) specific gravity of between 19 and 22 degrees. Although the primary purpose of the *P-36* was to support oil extraction, and not storage, a large quantity was present on and underneath the rig in pipelines, manifolds, and transfer vessels. In addition, 1,600 gallons (6,000 L) of diesel fuel, used to run engines and pumps, and a smaller quantity of lubricating oils, also were present in some quantity on the rig.

As the rig sank and its tanks and pipes were crushed and imploded by the pressure of the sea, the oil began to float to the surface and formed a thin but extensive slick. Petrobras applied chemical dispersants and attempted to deploy booms around the slick, but large waves made them ineffective. Fortunately, these same rough seas mixed and dispersed the slick, and the oil eventually formed tar balls and mousse—an emulsified mixture of water in oil. Mousse can range in color from dark brown to nearly red or tan and typically has a thickened or puddinglike consistency. The slick never reached the shore. Blowout preventers on the *P-36* wellhead had been connected properly and had sealed off the wells feeding oil to the rig. This prevented the overwhelming disaster that would have occurred if the dozen or so production wells that were connected to *P-36* had started releasing oil into the ocean. Ecological damage was minimal because the slick was far from sensitive shoreline habitats and currents and waves had worked quickly to dissipate it.

### AFTERMATH OF THE SPILL

The *P-36* rig was insured for \$500 million, and the claim filed by Petrobras was settled before the end of 2001. At the time of the *P-36* disaster, Petrobras was in the middle of an extensive expansion program, aggressively developing its reserves and pioneering

drilling and extraction technologies in deeper water. Some labor union officials and environmental organizations have claimed that in an effort to keep expanding its operations, Petrobras was paying less attention to safety. They point out that almost 100 Petrobras workers were killed in industrial accidents in the three years prior to the *P-36* incident, and 19 months later in October 2004, a second Petrobras platform, *P-34*, narrowly escaped sinking when an electrical failure shut down several crucial pumps and almost resulted in its capsizing.

Behind this intense hydrocarbon exploration and development effort was the political commitment by Brazil's leaders to make the country energy independent by 2005. The groundwork for this commitment to energy independence was laid in the 1970s when Brazil's economy was severely affected by the Organization of Petroleum Exporting Countries (OPEC) oil embargo. Vowing not to let itself become so vulnerable again, Brazil embarked on a serious program, not only to increase its oil reserves, but to find a practical substitute for gasoline. Being the world's largest producer of sugar, ethanol (ethyl alcohol) was quickly identified as the alternate fuel of choice. Fermented from sugarcane residues and heavily subsidized by the government, ethanol today accounts for almost 20 percent of the transport fuel used in the country and has developed into a multimillion-dollar industry. Ethanol exports from Brazil, particularly to Japan, were expected to reach more than \$1.3 billion by 2010. Thanks to this 30-year commitment to energy independence, farmers in Brazil can squeeze out 6,000 gallons (22,800 L) of ethanol for every 2.5 acres (1 ha) of planted sugarcane, and improvements in technology and crop selection are ongoing.

In the United States, which still imports 60 percent of its oil and where transport fuel-related uses of ethanol are less than 10 percent, the theoretical ethanol production from an equivalent corn field is only 4,000 gallons (15,142 L). The Energy Policy Act of 2005, however, increases the amount of ethanol and other biofuels that must be mixed with gasoline to triple the current amount being used to 7.5 billion gallons (28.4 billion L) by 2012.

**phosphorus** There are several enigmatic substances, especially inorganics, that are beneficial in certain forms and harmful in others. Perhaps the most extreme of these enigmas is the inorganic substance phosphorus. It is a primary component of bones and teeth in the human body, as well as adenosine triphosphate (ATP), and a necessary component for energy use in all cells of all living things. Some estimates place the average amount of phosphorus in a human body at more than one pound (0.45 kg). Phosphorus is one of the main reasons that humans can produce enough food to sustain their enormous population on Earth through its role in fertilizers. Yet the same substance is a major component in incendiary devices (bombs) and many other weapons, from tracer bullets to detonators. It is also a deadly poison and the primary component in several deadly nerve gases such as Sarin. How can it serve such different purposes? Simply put, if the phosphorus compound dissolves in water or aqueous solutions, it can be deadly; if not, it is beneficial. Phosphorus has been identified in 77 of the first 1,430 U.S. Environmental Protection Agency (EPA)-designated Superfund sites (National Priorities List) in which it was tested. It ranks 19th of the 275 most dangerous pollutants on the 2007 CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USE, AND PRODUCTION

Phosphorus was discovered in 1669, and phosphoric acid was discovered in 1770. It is the 11th most common element, making up approximately 0.12 percent of the Earth's crust. It is a nonmetal in the nitrogen family and occurs in white, red, and black varieties. In its pure form, white phosphorus is a colorless to white waxy solid with a garlic odor, but it is commonly yellow in its commercial form. When exposed to air, it is luminescent, though it was mistakenly

termed phosphorescent until 1974, when the glow was properly explained.

White phosphorus spontaneously ignites at approximately 104°F (40°C), making it highly unstable. It must be stored underwater, in many cases, to prevent accidents. As a result, it has limited uses. Military applications include tracer bullets, incendiary bombs and other devices, smoke screens, and detonators. Fluorophosphate is used to make nerve gas. Civilian and industrial applications include steel manufacture, in rodenticides including Bonide Blue Death Rat Killer and Rat-Nip, as well as in matches and fireworks in the past. The main use, however, is to produce phosphates and other compounds, which are used in everything from medicines to food additives and fertilizers and detergents, among many other uses.

Traditionally, the United States has been the highest consumer of phosphorus: more than 41.1 million tons (37.4 million metric tons) in 2002 and 42.5 million tons (38.6 million metric tons) in 2005. Domestic production was also the highest in the world through 2005, when it was 39.9 million tons (36.3 million metric tons), but it has fallen steadily to 29.9 million tons (27.2 million metric tons) in 2009. In 2006, China surpassed the United States as the largest phosphate rock producer. Florida and North Carolina produced more than 85 percent of the U.S. total, and the remainder was produced in Idaho and Utah. Imports of phosphate in 2005 were 2.9 million tons (2.6 million metric tons), which is about average over the past five years to 2009, 99 percent of it from Morocco. About 95 percent of the phosphate rock mined in the United States was used to manufacture phosphoric acid and superphosphoric acid, which were used as intermediates in the manufacture of granular and liquid ammonium phosphate fertilizers and animal feed supplements. Approximately 45 percent of the phosphoric acid was exported as granular phosphate fertilizer, merchant-grade phosphoric acid, and triple superphosphate fertilizer. The rest of the phosphate rock was used in the manufacture of elemental phosphorus.

### ENVIRONMENTAL RELEASE AND FATE

The fate of white phosphorus in the environment depends upon the conditions into which it is released. If released into water, elemental phosphorus quickly reacts to form several compounds. The rate of this degradation is primarily dependent upon the amount of dissolved oxygen, temperature, and pH of the water, and the removal half-life generally ranges from one hour to about 10 days. High values of the three factors promote breakdown reactions. The

reactions are also quicker in freshwater than salt water. The primary breakdown products are phosphorous pentoxide, phosphorous trioxide, orthophosphoric acid, phosphorous acid, and at times phosphine. Most of these products are much less toxic than phosphorus, except phosphine, which is a deadly toxin. The EPA has limited phosphine to 0.3 part per million (ppm) under the Safe Drinking Water Act. Even though white phosphorus is resistant to microbial degradation, its breakdown products are not and are further degraded. In anoxic conditions, phosphorus degrades very slowly, if at all, and settles into the bottom sediments. From there, it can be ingested by bottom feeders.

The mobility of white phosphorus in soil is low, but it depends upon availability of oxygen, size, depth of burial, and whether or not it is coated with another compound. Phosphorus can develop a surface oxide layer that protects it from further degradation. In this case, it can persist for many years. If it is buried deeply or is under anaerobic conditions, it may also be highly persistent. In most cases, however, phosphorus is oxidized in surface or shallow soils to phosphate compounds in a matter of weeks to months. The phosphates can then be leached into deeper soil horizons or be taken up by plants and animals.

Phosphorus is very toxic to most forms of wildlife. The first real case of ecological poisoning occurred in Placentia Bay, Newfoundland, where wastewater from a manufacturing plant in 1969 caused a huge fish kill. Subsequent studies showed that less than one part per billion (ppb) of phosphorus in water is toxic to most fish. It is also highly persistent in muscle tissue of fish, posing a health threat to consumers. A similar situation happened at the Pine Bluff Arsenal, Arkansas, where macroinvertebrates were killed. Perhaps the most famous ecological disaster occurred in Eagle River Flats, Alaska. As a result of artillery and munitions training, burned phosphorus was deposited from the smoke and fallout in a salt marsh. Migratory birds died off in the thousands after ingesting phosphorus in the sediment.

### HEALTH EFFECTS FROM EXPOSURE

There are many adverse health effects from exposure to phosphorus. Inhalation of white phosphorus results in cough and damage to the mouth in which wounds do not heal and there is a slow deterioration of the jaw and teeth coupled with intense pain. This condition is called phossy jaw. Even breathing smoke from phosphorus can damage the throat and lungs, and the smoke can irritate the eyes. Ingestion of white phosphorus in even small amounts (less than one tea-

spoon) can produce stomach cramps, vomiting, severe diarrhea with loss of blood, extreme fatigue, and damage to the stomach, intestines, liver, heart, and/or kidneys. It can also cause coma and ultimately death if the dose is higher than 0.00176–0.0035 ounce (50–100 milligrams). Being burned on the skin with white phosphorus can result in heart, liver, and kidney damage. Phosphorus is classified in group D, not classifiable as a human carcinogen, by the EPA.

### REGULATIONS ON HUMAN EXPOSURE

The EPA requires the reporting of any environmental release of white phosphorus of one pound (0.45 kg) or more to the National Response Center. The Occupational Safety and Health Administration (OSHA) and National Institute of Occupational Safety and Health (NIOSH) restrict the amount of phosphorus in workplace air to 0.1 mg per cubic meter for an eight-hour-day, 40-hour workweek. NIOSH has set a designation of immediately dangerous to life and health (IDLH) for any exposure of 5 mg of phosphorus per cubic meter of workplace air.

**phthalate** Although this very high-volume chemical generally has relatively low toxicity, phthalate was at the center of a great public health controversy. Phthalates are primarily used as plasticizers in plastics to make them soft and supple. A major use for some of them was in teething rings, pacifiers, and other infant devices. It was found, however, that the phthalate could separate and leak out of the plastic

under certain conditions, such as being chewed. As a result of the ensuing public outcry, it was banned from all infant devices in 1999. That, however, was not the end of trouble for phthalates. They are also commonly used in medical devices such as intravenous tubing and bags. Outright bans have not been enforced because the threat is not universally recognized. At present, precautions are taken with certain at-risk populations such as infants, hemophiliacs, and kidney disorder patients.

There are many types of phthalates. The most commonly used phthalates are DEHP (di-2-ethyl hexyl phthalate), DIDP (diisodecyl phthalate), DINP (diisononyl phthalate), DNOP (di-n-octylphthalate), BBP (butyl benzyl phthalate), DBP (di-n-butyl phthalate), BzBP (benzylbutyl phthalate), DAP (diallyl phthalate), and DEP (diethyl phthalate). In the first 1,613 hazardous waste sites that the U.S. Environmental Protection Agency (EPA) assigned to the National Priorities List (Superfund sites), 733 were found to contain DEHP, though not all may have been evaluated for them. DBP was found in 471 of the first 1,585 sites, and DEP was found in 248 of the first 1,397 sites. In terms of the 275 most dangerous pollutants on the 2007 CERCLA Priority List of Hazardous Substances, DBP ranks 52nd, DEHP ranks 76th, BBP ranks 195th, and bis-(2 methoxyethyl) phthalate ranks 194th.

### PROPERTIES, USES, AND PRODUCTION

Phthalates are synthesized organic compounds that do not occur in nature. They are generally clear, colorless to slightly yellow liquids that do not evaporate readily. Phthalates were first produced in the 1920s, and some 1 billion pounds (454 million kg) was produced in 2004. Production of dioctyl phthalates alone ranged from 309 to 285 million pounds (140–130 million kg) per year from 1990 to 1998. Imports of dioctyl phthalates were 18 million pounds (8.2 million kg) in 1985 and 6 million pounds (2.7 million kg) in 1986 and 1988. In 1998, 4 million pounds (1.8 million kg) was imported, and between 14 and 27 million pounds (6.4 and 12.3 million kg) per year was exported from 1994 to 1998. They are a very high-volume product. The larger-molecule phthalates are primarily used as plasticizers in all kinds of plastics for all kinds of applications, whereas the smaller-molecule varieties are used for a number of different applications. These include solvents in perfume, nail polish, adhesives, lubricants, soap, shampoo, hairspray, pill coatings, detergents, wood finish, pesticides, paint pigments, rocket fuel, and many others.

DEHP is the most common of the phthalates. About 95 percent of DEHP is used as plasticizer in

polyvinyl chloride (PVC) to produce flexible vinyl products. DEHP is also known commercially as BEHP, Dioctyl phthalate, Pittsburgh PX-138, Platinol AH, RC Plasticizer DOP, Reomol D79P, Sicol 150, Stafflex DOP, Truflex DOP, Vestinol AH, Vini-cizer 80, Palatinol AH, Hercoflex 260, Kodaflex DOP, Mollan O, Nuoplaz DOP, Octoil, Eviplast 80, Fleximel, Flexol DOP, Good-rite GP264, Hatcol DOP, Ergoplast FDO, DAF 68, and Bisoflex 81. DEHP was first developed in the United States in 1939, but commercial production did not peak until the mid-1980s. Domestic production was 251 million pounds (114,000 metric tons) in 1982 and 286 million pounds (130,000 metric tons) in 1986. By 1994, production had begun to decline to approximately 258 million pounds (117,500 metric tons).

More than 17 million pounds (7.8 million kg) of DBP, a small-molecule but dangerous phthalate, was produced in 1994. More than 10 million pounds (4 million kg) of pure DNOP was also produced in 1994; it was most commonly used in a compound of 20 percent strength as a plasticizer.

### ENVIRONMENTAL RELEASE AND FATE

Phthalates are largely released as point source pollutants as spills during production, transport, and storage/disposal or as a result of improper handling and disposal or incineration of plastic. There is not much information about interaction of phthalates with the environment. DEHP is probably the best studied, although there are some preliminary and site-specific studies on others that indicate a similar response. DEHP has a strong tendency to adsorb to soil and sediments and, therefore, tends not to leach into groundwater. It appears to biodegrade in soil under aerobic conditions after a period of acclimation. If released to water, DEHP biodegrades rapidly with a removal half-life of two to three weeks after a period of acclimation. If released to air, DEHP is carried long distances and may be removed by precipitation wash-out. DEHP can bioconcentrate in aquatic organisms at experimental factors ranging from 2 to 4.

According to EPA's Toxic Chemical Release Inventory of 1987–93, DEHP releases to land and water totaled more than 500,000 pounds (227,272 kg), about 95 percent of which was to land. The largest releases in the United States occurred in Wisconsin, Tennessee, Ohio, New Jersey, and New York.

### HEALTH EFFECTS FROM EXPOSURE

All of the phthalates have a similar series of adverse health effects from similarly high levels of exposure. At low levels, they have low toxicity, but extreme

levels may be fatal. Acute exposure to DEHP may potentially cause mild gastrointestinal disturbances, nausea, and vertigo. Chronic exposure has the potential to cause damage to liver, kidneys, lungs, endocrine and blood systems, thyroid and testes, as well as producing negative reproductive effects. The real danger of DEHP is that it leaches from medical plastic bags and hoses into intravenous fluid treatments and even blood. It is estimated that DEHP occurs in concentrations of nine to 13 parts per billion (ppb) in intravenous (IV) fluids and 14–120 parts per million (ppm) in stored blood. On the one hand, for most people who have short exposures, these concentrations do not present an immediate or serious health threat. On the other hand, some people are sensitive to DEHP and can have severe adverse reactions to exposure. In addition, the Department of Health and Human Services considers DEHP to be reasonably anticipated to be a human carcinogen, on the basis of sufficient evidence of carcinogenicity in experimental animals, in which it greatly increased the incidence of liver cancer. The EPA considers it a probable human carcinogen, although the International Agency for Research on Cancer downgraded DEHP to not classifiable as a human carcinogen in 2000. People who require prolonged or repeated medical treatment with plastic hoses and bags may have an additional risk of cancer.

Of the other phthalates, most are of low toxicity except under extreme exposure. DNOP can cause some liver damage or even be fatal at extreme concentrations or, under low to moderate concentrations, be mildly irritating to skin and eyes. If pregnant female laboratory animals are exposed to extreme concentrations, it has also been shown to cause reduced litter size, increased fetal malformations, and developmental effects. DEP has been shown to have virtually the same effects. At extreme concentrations, exposure to BBP causes reduced body weight, reproductive and developmental damage, and an increased incidence of mononuclear cell leukemias in laboratory animals. Under these same conditions, exposure to DAP increased the incidence of chronic liver disease, incidence of lymphoma in males and mononuclear cell leukemia in both genders, and damage to the forestomach in laboratory animals. DBP, under these conditions, can temporarily reduce male fertility, as well as causing skin and eye irritation.

### REGULATIONS ON HUMAN EXPOSURE

Federal agencies regulate worker and general exposure to phthalates as the result of these health risks. The EPA limits the amount of DEHP in drinking

water to six parts per billion (ppb) under the Safe Drinking Water Act. They further require the reporting of any environmental release of 100 pounds (45 kg) or more to the National Response Center. The Occupational Safety and Health Administration (OSHA) restricts the amount of DEHP in workplace air (PEL) to 5 mg per cubic meter for an eight-hour-day, 40-hour workweek. The OSHA short-term exposure limit (STEL) is 10 mg per cubic meter for no more than 15 minutes. The National Institute of Occupational Safety and Health (NIOSH) has set the same general exposure limit (REL) and short-term exposure limit (STEL) as OSHA and a designation of immediately dangerous to life and health (IDLH) for any exposure of 5,000 mg of DEHP per cubic meter of workplace air. NIOSH estimates that about 340,000 workers, including 106,900 women, were potentially exposed to DEHP in the early 1980s.

Regulations on the other phthalates are not as complete or as stringent as they are for DEHP. The EPA limits the amount of DBP in drinking water to 34 ppm but requires the reporting of any release of 10 pounds (4.5 kg) or more. NIOSH restricts the amount of DBP to 5 mg per cubic meter of workplace air for an eight-hour-day, 40-hour workweek. Exposure of workers to DEP is limited by both OSHA and NIOSH to 5 mg per cubic meter for an eight-hour-day, 40-hour workweek. As many as 239,000 workers may have been exposed to DEP. Although NIOSH estimates that 10,393 workers were exposed to DNOP in 1980, there are no regulations on human exposure.

**phytotoxicity** Compounds or substances that damage or injure a plant are called phytotoxic (*phyto*, from the Greek word for “plant”). Phytotoxicity most commonly results from the overuse or improper application of pesticides, herbicides, or fertilizers. Many industrial wastes and pollutants such as heavy metals, petroleum compounds, and organic chemicals, however, can also be phytotoxic. Even irrigation, unless proper techniques are followed, can cause natural salt levels to rise so high that plant growth cannot be sustained. Phytotox-

icity occurs with organic chemicals, such as pesticides or petroleum compounds, if the contaminant diffuses into the phloem (food-conducting tissue) or xylem (woody tissue) of the plant. Once there, the phytotoxin disrupts cell membranes, blocking nutrient uptake and slowing plant growth. Although inorganic compounds such as metals and salts are needed in trace amounts for normal plant growth, at excessive concentrations they are enzyme inhibitors, interfering with the plant's basic metabolic systems. Phytotoxicity can express itself in three ways:

1. Stunting or delayed plant maturation.  
This phytotoxic effect becomes apparent when plants are not growing at their typical rate or are not as developed or robust as they should be at certain points in their growing cycle. Excess lead and copper levels in soil can cause stunting in plants.
2. Morphological distortion.  
Another indication of phytotoxicity is identified when plants and their leaves, flowers, or fruits are misshapen or distorted. Exposure to high levels of atmospheric hydrocarbons, ozone, and sulfur oxides can bend or twist leaves on many types of plants.

### PHYTOTOXIC EFFECTS OF COMMON INDUSTRIAL POLLUTANTS

Contaminant	Effect
Arsenic	Wilting of new cycle leaves followed by retardation of root and top growth and leaf necrosis (death).
Cadmium	Reduces photosynthetic rates, interferes with root system development, and damages the ability of stems to transmit water or sap to leaves.
Chromium	Stunted growth, poorly developed roots, and leaf curling. May interfere with metabolism of C, N, P, and Fe, as well as certain plant enzymes.
Lead	Usually concentrated in root and related root structures. Affects mitochondrial respiration and photosynthesis.
Naphthalene	Reduction in new or young plant growth weights.
Nickel	Blocks nutrient absorption by roots and inhibits photosynthesis and transpiration. Also can induce chlorosis (yellowing of plant tissue) and foliar (leaf) necrosis.
PCBs	Reductions in plant growth caused by interference with transpiration (water uptake) mechanisms.
PCP	Reductions in plant growth caused by interference with transpiration (water uptake) mechanisms.
Toluene	Negatively affects seed germination and plant weight. Toxic effect appears to be acute because toluene is not accumulated in plants.
Uranium	Disrupts plant enzyme systems and may interfere with nucleic acid formation. The very low levels of radiation emitted by natural uranium absorbed by the plant do not play a significant role in phytotoxic effects.

## 3. Russetting or bronzing.

When the leaves or fruit of a plant have yellowed or turned reddish brown (russeted), or have dead spots on their tips or margins, or have dead areas between the veins, then phytotoxicity is the likely cause. Pesticides and herbicides, if overused or not properly applied, can cause these symptoms of phytotoxicity.

An examination of the leaf provides the best way to distinguish between phytotoxicity and disease, poor soil conditions, or other forms of natural plant distress. If the injured leaf tissue is sharply defined with little or no color gradation between dead areas and healthy areas, then phytotoxicity is the likely cause. If damaged areas appear across the leaf as patches or in sections, then other causes of injury (dehydration, disease) should be suspected. These symptoms of phytotoxicity, stunted growth, misshapen or twisted leaves, and fruit russetting or bronzing, are collectively called signs of distressed or stressed vegetation and are often used during hazardous waste site investigations to help delineate, or map out, the extent of contamination.

The most striking examples of phytotoxicity occur near mines. Debris and residues generated during extraction and processing of coal, copper, iron, gypsum, and other minerals can cause significant environmental damage.

**Piper Alpha oil spill North Sea, United Kingdom (July 6, 1988) Water Pollution**

Of the 40 most costly insurance claims filed between 1970 and 2005, there were only two that were not related to a natural disaster such as an earthquake, flood, or hurricane: the 9/11 World Trade Center attacks and the *Piper Alpha* platform disaster. The 1988 explosion and fire on the *Piper Alpha* platform killed 167 people (including two rescue personnel) and cost more than \$3.3 billion. It also resulted in major changes to safety procedures and protocols being used by those companies drilling for oil and natural gas in the North Sea.

**BACKGROUND**

*Piper Alpha* was first placed into service on the North Sea as an oil platform in 1976. Later converted primarily to recover and process natural gas, the platform had a working surface that extended more than 100 feet (30.5 m) above the choppy and frigid ocean waters. It was divided into three sections: a drilling derrick on one side, a processing and refining area taking up the center part of the platform, and crew accommodations at the other end. The rig and production platform (added later) were operated by OPCAL, or Occidental Petroleum (Caledonia) Ltd. OPCAL was part of a larger company—the Occidental Petroleum Corporation. More commonly known as Oxy, the Occidental Petroleum Corporation is an international oil and gas exploration and production firm with business interests and facilities in the United States, Middle East, North Africa, and Latin America. Oxy is the fourth largest U.S. oil and gas company and is a wholly owned subsidiary of Occidental Chemical Corporation (OxyChem), one of the world's largest manufacturers of chlor-alkali and vinyl. Oxy also is the largest oil producer in Texas and the largest natural gas producer in California. Although strongly committed to operating its businesses in accordance with all environmental laws and regulations, Oxy currently has been named as a responsible party in more than 130 federal or state equivalent Superfund actions, largely as a result of prior or legacy operations.

Three other experienced oil companies joined OPCAL as business partners in financing the extraction of oil from the Alpha well field: Texaco Britain Ltd (23.5 percent share of both expenses and revenues), Union Texas Petroleum Ltd (20 percent share), and Thomson North Sea Ltd (20 percent share). OPCAL (36.5 percent share), however, was responsible for operating the *Piper Alpha* rig in a safe and environmentally responsible manner. Although the

exact date is uncertain, there is general agreement that by the end of 1976 *Piper Alpha* was on station in approximately 470 feet (143.3 m) of water in the Piper Field, 120 miles (193 km) northeast of Aberdeen, Scotland, and producing oil from a 12-square-mile (31-km<sup>2</sup>) reservoir 8,000 feet (2,438 m) below sea level. By 1988, 226 people living and working on the platform for weeks at a time were extracting natural gas and some oil from 24 producing wells.

*Piper Alpha* was a fixed platform, anchored to the seabed on each corner by massive columns that had been attached to the submarine bedrock by skirt piles. These are sleeves arranged in a circular pattern around the column or jacket through which a supporting column or pile is driven, eventually resting on the bedrock. The jacket then is connected to the piles and the platform is secured in place. The deck support frame is attached to the jacket and the four main areas or modules of the *Piper Alpha* platform assembled: Modules B and C were the main production or working modules and Module D was the generation and utilities module. Other modules, built higher up on the deck frame, included the Mud Module, Storage Module, and Gas Conservation Module. Crew quarters were at the north end of the platform some 120–175 feet (36.6–53.3 m) above the ocean surface. All of the modules were separated by firewalls, and the living areas were placed as far from hydrocarbon recovery and production areas as possible.

At its peak, *Piper Alpha* was producing oil at the rate of approximately 300,000 barrels (12.6 million gallons [47.9 million L]) per day, about 10 percent of the total amount of oil from British fields in the North Sea, with a value of more than \$5 million per day. OPCAL and its partners built a storage terminal on the Orkney Islands and connected it to the *Piper Alpha* platform via a 30-inch- (0.76-m-) diameter, 128-mile- (206-km-) long pipeline. By 1980, oil yields had started to decline, and OPCAL decided to focus more on the recovery of natural gas or methane, a major component of the dissolved gases that were present in the oil from this field. In addition, the recovered gas contained several different types of volatile hydrocarbon condensates: propane, butane, and pentane. These condensates have high vapor pressures and low flash points and, along with the methane, were being discharged into the *Piper Alpha* wells at an impressive natural pressure of approximately 3,400 pounds per square inch (23,442 kPa).

*Piper Alpha* collected gas from its 24 wells in two large-diameter riser pipes that extended up through the platform from the seafloor. Machinery on the platform condensed, or separated, the liquid pro-

pane, butane, and pentane, and then discharged the methane gas into separate 18-inch- (46-cm-) diameter pipelines that fed both another platform and a gas compressing station anchored 30 miles (48 km) to the northwest. The physical alterations that had to be made to the *Piper Alpha* platform to accommodate its new natural gas mission resulted in significant compromises to its safety systems: The natural gas compression system was installed adjacent to the platform's control room, the structural steel members of the platform were not fireproofed, and emergency shutoff valves on the gas riser pipes left large amounts of residual gas in the lines upstream of the valves, even after they were closed. These inherent design and system flaws might have been manageable if a strong safety culture existed on the platform. Several postdisaster studies, however, indicated that neither company management nor line workers took safety and accident prevention seriously.

Emergency evacuation drills were rarely held, and safety training for visitors, temporary subcontractors, and regular platform workers was not conducted with any regularity. The platform's sprinkler and deluge fire control systems were in need of repair and replacement, and the diesel-powered fire pumps usually were in manual control mode, in violation of platform safety procedures. These pumps could flood the platform with massive amounts of seawater in the event of a fire, but workers would set them on manual mode so divers would not be pulled into the intake manifolds if they started automatically. Maintenance and repair staff would either forget or elect not to restore the pump settings to automatic mode. Once the pump was set on manual, in an emergency a trained operator would have to go to the pump's control panels and turn them on to provide water to the deluge system.

Most importantly, the platform's permit to work (PTW) system procedure was often not followed and, in many cases, completely ignored. A PTW system is a formal written set of procedures intended to identify and manage safety risks associated with certain potentially highly hazardous activities. It describes how the work is to be performed and the precautions that must be followed in completing the task. It also informs those performing the work, as well as their supervisors, managers, and colleagues, that a high-hazard task is under way and that only adequately trained personnel should be involved in the work. Finally, the PTW requires that the work be audited or inspected during and after its completion. On an oil production platform such as *Piper Alpha*, PTWs would be issued for such activities as welding, opening pressurized lines, and entering confined spaces. *Piper Alpha*'s PTW system appar-

Smoke pours from the burning *Piper Alpha* oil platform in the North Sea off the coast of Scotland, July 8, 1988 (AP Images)

ently was only sporadically enforced. Required sign-offs before and after the work were seldom obtained, results of gas monitoring not documented, and job-site inspections not done.

### ACCIDENT AND SPILL

In 1988, *Piper Alpha* was the oldest of the 120 or so oil rigs and platforms being operated in the United Kingdom's North Sea territorial waters, and its age, inadequate design, and lack of safety culture led to disaster. On July 6, 1988, a maintenance crew started to repair a backup, or secondary, condensate pump connected to one of the platform's two main gas riser pipes. They disconnected a relief valve from the pump but were not able to finish the repair before the shift ended. Rather than allowing the work to be completed at the overtime rate, the supervisor directed that a blind flange be placed over the opening where the relief valve had been connected to the main gas riser pipe. A blind flange is a solid metal disk that is bolted onto the end of a pipe or fitting as a seal. The maintenance crew was in a hurry, and the pipe was not being used anyway, so they only loosely attached the blind flange to the

gas riser. The PTW permit, partially filled out, was dropped on a desk in the control room as the crew ended their workday. They did not indicate that the work was incomplete and that the required installation of the blind flange had not been performed. The maintenance crew, which had not been properly trained in safety procedures, also did not mention to the platform operator that the secondary compressor pump had not been repaired and was still out of service.

Just before 10:00 p.m., the primary condensate pump on one of the main gas risers failed, and the platform operator switched to the secondary pump—the one from which the relief valve had been removed. Gas and oil began to gush at incredible force from the partially installed blind flange and made a noise that several survivors described as the “screaming of a banshee.” The gas formed a large flammable cloud over the platform, found a source of ignition, and exploded. This explosion tore apart oil lines, and burning oil spilled into the sea. The fire continued to be fed by both residual gases present in internal lines of the platform and other platforms that sent their gas to *Piper Alpha*. Although operators on these other platforms could

see a problem on *Piper Alpha*, without instructions to shut down the flow of gas, they continued to feed methane to the burning rig. It was nearly one hour before platform operators shut down gas transfer operations to *Piper Alpha*.

Without an adequate deluge system and with the fire pumps inactivated (no one could get close enough to the controls to turn them on), the fire burned essentially out of control and began to weaken the structural steel of the platform. One estimate placed the rate of natural gas being burned in the fire as that being used by all of Great Britain. Workers fled to the crew modules, to await rescue. The intensity of the flames, however, hindered evacuation efforts. The flames and smoke were too intense to allow helicopter landings (the heat from the 300-foot- [91.4-m-] high flames could be felt one mile [1.6 km] away), and the rescue boat permanently assigned to the platform had to move out to sea in order to avoid catching fire.

The noise, smoke, lack of emergency evacuation training, and poor communication system resulted in general confusion among those gathered in the crew's quarters. As the fire approached that end of the platform, workers faced a terrible decision: either stay in the accommodations module and hope for rescue or jump more than 125 feet (38.1 m) through a burning pool of oil that had accumulated at the base of the platform and into the freezing waters of the North Sea. "Fly or fry" was the way one survivor phrased the choice.

Of those who jumped, many perished, but 62 were rescued, most with severe injuries and burns, by Royal Navy and other ships that had quickly assembled. Of the 165 people who died on the platform or in the water, many (81 in all) were killed by smoke inhalation while lying on the floor in the accommodations module with wet rags and towels over their nose and mouth.

Within three hours of the initial explosion, the billion-dollar *Piper Alpha* platform was lost, melted, and sinking with a roiling hiss into the North Sea, taking the dead and dying with it. The relatively minor amount of oil released into the ocean from the platform's burst lines did not create a significant ecological hazard. *Piper Alpha* was more than 100 miles (161 km) away from sensitive shoreline habitats, and the platform's below-water automatic shut-down valves had functioned well. Insurance reimbursed OPCAL for the destruction of the platform as well as for lost production. Approximately \$700,000 in compensation also was paid to each of the families of those killed or severely injured by the disaster.

## THE AFTERMATH

The loss of the *Piper Alpha* badly shook the confidence of both the oil industry and the British government about the safety of its North Sea hydrocarbon exploration and extraction operations. The inquiry convened after the disaster made several recommendations that, when finally implemented, fundamentally changed the approach to offshore platform design, management, and safety. A new government agency was formed: the Health & Safety Executive (H&SE). This agency's mission is specifically focused on developing and implementing programs and policies to minimize risks to those working on offshore platforms and drilling rigs. To accomplish this, the H&SE frequently inspects oil platforms, audits their operations and procedures, and aggressively investigates accidents and worker complaints.

As part of the overhaul of the regulatory system that governed platform operations, new goal-setting or performance-based rules were enacted. These new rules replaced highly specific or dogmatic directives with ones that allowed for greater flexibility and assigned more responsibility in the design of platform safety systems. For example, instead of requiring that a platform be made of a specified grade and thickness of steel, the new goal-setting regulations simply required that a platform had to be able to withstand a certain temperature for a given period without failing; the material it was made of was not important, so long as it could meet the performance standard. This approach allowed for much more creativity in the incorporation of safety systems into platform design.

The final major change to offshore safety was the requirement that any company operating in this arena had to have an effective and meaningful safety management system, or SMS. Such a system must set objective performance standards for platform operations and be able to demonstrate that the offshore installation is designed to operate in a safe manner with the major risks to workers minimized. As part of the SMS, quantitative risk assessments (QRAs) must be performed on all aspects of platform design and operation in order to collect structured, objective, numerical data. These data then can be applied to the measurement of risk in order to make clear comparisons of the effectiveness of safety methods. In other words, a QRA numerically demonstrates how probable a harmful event is and how severe a particular consequence would be as a result of using a certain safety measure.

The sad lessons of *Piper Alpha* have not been lost on those companies that drill and extract oil from under the sea, and this vital industry's safety record

has improved dramatically since the 1988 disaster. However, paraphrasing Lord William Douglas Cullen, the Scottish judge who oversaw the public inquiry into the *Piper Alpha* catastrophe, the fire and explosion were not an accident, but rather an abrogation of the responsibility of the platform's owners and operators to provide a safe working environment to those people who had entrusted their lives and health to them.

**plastic trash in the oceans** Plastic trash can be seen virtually everywhere on every beach at any time. There are two reasons: People generate huge amounts of plastic trash and it is virtually indestructible. The production of plastic in the United States was roughly 3 million tons (2.7 million metric tons) in 1960 and 50 million tons (45.5 million metric tons) by 2000. A good proportion of that production is purely waste, and recycling programs are not widespread or adhered to enough to prevent it from being at least an eyesore, if not a hazard. Much of the plastic waste enters marine environments, where it is especially destructive. It is estimated that the navy, merchant vessels, and fishing vessels dump more than 135,000 tons (122,727 metric tons) of plastic trash directly into the ocean as waste. The National Academy of Science estimated that the commercial fishing industry loses or discards some 149,000 tons (135,455 metric tons) of fishing gear

on an annual basis. This gear, including ropes, nets, buoys, and traps, is largely plastic. The industry also dumps 26,000 tons (23,636 metric tons) of plastic packaging material annually. More than 7 million tons (6.4 million metric tons) of waste is also added from cargo and cruise ships per year. In addition, recreational vessels and the oil industry contribute significant amounts of waste depending upon the year. Plastic trash is a worldwide problem, as it is produced everywhere and found everywhere.

Plastic is nearly indestructible and, therefore, may pose a threat to the environment for hundreds of years. Under the right conditions, it is estimated that an ordinary plastic six-pack ring can persist for 450 years. With the abundance and durability of this material, which was certainly not designed to be environmentally friendly, plastic waste has become a hazard to many marine animals. It is estimated that as many as 30,000 fur seals die per year as a result of becoming tangled in discarded plastic fishing nets or choking on plastic cargo straps. Lobster and crab traps are entirely or partly constructed of plastic and are efficient at trapping their prey. The problem is that lost traps continue to trap prey even though no one empties them. It is estimated that in one year, some 25 percent of the 96,000 set off the west coast of Florida were lost as a result of storms or carelessness. Plastic bags and sheets suffocate whales, porpoises, and coral by covering or entangling them, and sea turtles die of eating them. Seabirds die after getting entangled in six-pack rings and fishing line, as do some marine mammals. Plastic trash is as great a danger to marine life as oil spills, toxic waste, and heavy metals.

To combat this grave danger, the Marine Plastic Pollution and Control Act of 1987 was signed into law and enforced by the U.S. Coast Guard in U.S. waters. The law prohibits the dumping of plastic debris from ships for any reason. Other waste may be dumped beyond a certain limit, and ports must provide waste facilities. Some companies have begun to use plastics that degrade when exposed to sunlight, but sunken biodegradable plastic lasts just as long as nonbiodegradable plastic. Considering the immense amount of plastic waste generated by beachgoers and beach/shore communities, it does not appear that this problem will be resolved anytime soon.

### point source and nonpoint source pollution

All pollutants are emitted to the environment, whether to air, water, or soil, either from point sources or from nonpoint sources. The basic difference between the two is that point source pollution has a single source or grouped sources that can be identified, whereas nonpoint source pollution is produced by numerous diffuse sources that may not be easily identified. Point source pollution typically occurs at much higher concentrations than nonpoint source pollution. The sources themselves are very different, and even the pollutants are generally different, though there can be significant overlap. It is the specific details of the individual cases of pollution that determine which of the two is the source.

### POINT SOURCE POLLUTION

Point source pollution can be devastating to the public health and environment in a specific area, but it is usually not extensive in area. Although the concentration of the pollutant is generally high, the total volume of the release is generally small compared with that of nonpoint sources. Point source pollution is most common in groundwater; it can be from Superfund sites, landfills, leaking underground storage tanks (USTs) from gas stations, houses or industry, broken pipelines, septic systems, industrial spills, military facilities, waste pits and lagoons, mines, and other sources, where all of the pollution has a single identifiable location. The type of pollution is relatively unique for several of these sources.

Fuel is the most common point source pollutant in groundwater, whether home heating oil, diesel, or gasoline, but it can also be from a nonpoint source. It most commonly leaks from USTs at gas stations and homes with oil heat. Other point source pollution in groundwater can be caused by industrial

chemicals. Common pollutants include tetrachloroethylene (PCE), which is mainly from dry cleaners; trichloroethylene (TCE), which is a solvent used in degreasing; and methyltert-butylether (MTBE), which was used in fuel, among many others.

Fuel may also be the most common point source pollutant in surface water. Oil spills from tanker accidents, oil well blowouts, and oil transfer spills are more common in marine waters, and raw sewage is probably more common in rivers. In the United States, raw sewage in rivers is less common today but was very common in the past. Animal waste from stockyards may be more common today but it is usually only a problem during storms and floods. Acid mine drainage (AMD) is common around many types of mines and is composed of sulfuric acid, which lowers the pH of the surface water body into which it empties. AMD dissolves the minerals out of the mine wastes, and, as a result, there is heavy metal contamination as well. Mines and mineral processing facilities can also cause pollution of surface waters through suspended particles of heavy metals and other pollutants in surface runoff. Gold processing can even produce cyanide as a point source pollutant.

Soil pollution from a point source is typically found where there is groundwater pollution from a point source because the liquid pollutant must leach through the soil to reach the groundwater, and some adheres to the soil particles or is trapped in the pore spaces. Soil pollution is also common at mines and provides the source of pollutants for the runoff to remove during storms and floods. Animal stockyards are point sources for soil pollution as well. These examples are linked to point source pollution of other media. Soil, however, may also contain point source pollution that does not affect or only marginally affects the other types. Prior to the Resource Conservation and Recovery Act (RCRA), landfills could have been buried directly into soil without any containment. Depending upon the waste and climate, the landfills may affect groundwater, as well. In many industries, waste metals were simply dumped behind or around the manufacturing facilities. Materials such as chromium, mercury, lead, nickel, and even radium were simply dumped into holes or even on the surface. Until such time as these wastes are physically removed, they remain at the sites indefinitely.

Point source pollution into the air is probably the most noticeable to the general public. Smokestacks belching out dark-colored smoke at incinerators, coal-fired power plants, oil refineries, steel and metal refineries, and any other stationary source are probably the most visible. These sources produce

## DEICING CHEMICALS AND THE ENVIRONMENT

The transportation of goods and the ability of people to move in a safe and efficient manner are essential to ensuring an adequate distribution of resources, capital, and intellectual assets, which are key components of every country's economy. The Romans built and maintained a complex system of roads to ensure rapid deployment of troops and easy import and export of goods to its population centers. The Inca developed a 14,000-mile- (22,500-km-) long sequence of trails and paths through the Andes Mountains that connected cities in Chile and Ecuador with their capital in Peru. The Chinese constructed the Gansu Corridor, part of a major transportation system called the Silk Road, a 740-mile (1,200-km) improved and, in places, paved, trail that connected the massive country's western borderlands and the Yellow River (Huang Ho) valley, the birthplace of Chinese civilization.

The United States developed an extensive interstate highway system during the late 1950s through the early 1990s. It was not, however, for the convenience of working commuters or for the speeding of tourists to vacation destinations but instead for national defense and interstate commerce. The main appropriations bill that established the National Highway Trust Fund through a federal tax on retail gaso-

line sales and began the era of interstate highway construction was called the National Interstate and Defense Highways Act of 1956. Originally envisioned as providing evacuation routes from major cities in the event of nuclear attack, interstate highways also were designed to allow for the movement of troops and materials in the event of invasion or widespread civil unrest. In fact, portions of Interstate 80, the main east-west highway connecting New York to San Francisco, has been designed in places to serve as emergency runways for the B-52, America's long-range bomber. Reportedly even today, late at night, sections of Interstate 80 are closed occasionally so that B-52s can practice "touch and go's" on the highway. The 47,000 miles (75,600 km) of the U.S. interstate highway system required 35 years to complete and cost more than \$420 billion.

But complicating the operation and maintenance of the interstate highway system is the weather. Route 80, as well as all the other roads and highways built in the northern three-quarters of the country, is occasionally covered with ice and snow. Snow can be removed physically, but ice tends to coat the roadways, and it is dangerously slippery and responsible for numerous serious accidents every year. To

Loading road salt in Columbus, Ohio, ca. 2007 (AP Images)

keep highways and roads open and safely passable, a variety of deicing agents are liberally applied to their surfaces, and each of these compounds has an associated environmental effect.

### ROCK SALT

Rock salt, or halite (NaCl), is the most commonly used deicing compound. It also is the most environmentally damaging. Rock salt is different from table salt in that after mining, the halite that is to become table salt is dissolved into a brine solution and then recrystallized as a fine white uniform mass. Supplements, such as iodine, are added to it before packaging for retail sale. Salt is essential for human health because it balances the flow of nutrients into and out of cells and helps regulate blood pressure and central nervous system functions. But human tolerances for this compound are fairly narrow. An excess of salt can cause hypertension (high blood pressure), edema (fluid retention), gastrointestinal ulcers, and cardiovascular disease. A lack of salt can result in dizziness, muscle cramps, and even fatal neurological damage.

Water that is salty (has a chloride concentration greater than 35,000 mg/L) is not potable and cannot be used for agricultural or other industrial or commercial purposes. Freshwater is defined as having a chloride concentration of less than 1,000 mg/L, but the U.S. Environmental Protection Agency sets a limit on chloride concentration in water to be used for drinking of 250 mg/L. One teaspoon of salt dissolved in 5.6 gallons (21.2 L) of water results in a chloride concentration of 280 mg/L.

Readily available and inexpensive (about \$50 per ton or three cents per pound), rock salt lowers the temperature at which water freezes, thus preventing the formation of ice. In pure water, ice forms at 32°F (0°C), but when salt or any compound that is soluble in water is added, the temperature at which water freezes drops. This is because the bonded oxygen and hydrogen atoms present in liquid water move more rapidly than those same paired atoms in ice. As heat is removed from the liquid water, the movement of the oxygen and hydrogen molecules slows, until, when the freezing point is reached, the motion is slow enough to allow the formation of solid ice. When salt is added to water, the salt and water molecules combine, and more heat must be removed to slow their movement, freeze (stop), and separate these larger salt and water molecules. This means that the temperature at which salty water freezes is lower than that of pure water.

A solution of 90 percent water and 10 percent salt (10 percent salt solution) freezes at approximately

Graph showing the temperatures of the freezing-melting curve for water as a function of concentration of salt (NaCl)

20°F (-6°C), and a 20 percent solution freezes at 2°F (-16°C). This means that, unless it is very cold, the addition of salt to a road's surface will melt or soften the ice and allow it to be scraped easily off by a plow. At very low temperatures, below approximately 15°F, the salt cannot penetrate into the ice structure, and very little or even no melting will take place. At those or lower temperatures, the use of abrasive (i.e., sand) to improve tire traction is a more effective ice management solution.

Salty water is electrically conductive because of the dissolved sodium and chloride ions; as a result, it hastens galvanic corrosion. This is a type of metal degradation or rust that occurs whenever two different types of metals, such as steel and aluminum, are in contact with an electrolyte such as salty water. The two metals act essentially as terminals on a battery, and the salt water acts as a wire between them. This causes rapid deterioration of the metal as low levels of electrical current flow from one through the other. This is the reason that cars and trucks in northern climates deteriorate more quickly than those in the South.

More than 15 million tons (13.6 metric tons) of salt is applied annually to roadways in the United States. This total includes the less aggressive but still environmentally damaging salts of magnesium chloride (MgCl<sub>2</sub>) and calcium chloride (CaCl<sub>2</sub>). On roads where salt is spread to control icing, environmental stud-

ies show that soil, vegetation, surface water and groundwater, as well as such highway facilities as guard rails, bridges, and concrete, and vehicles can be adversely affected. The majority of soil and vegetation damage occurs within 50–100 feet (15–30 m) of the road and is greatest close to the pavement, but salty runoff from highways can contaminate underlying aquifers, as well as nearby streams and rivers. At Mirror Lake in the White Mountains of New Hampshire, one study found that chloride concentrations had increased 10-fold after the opening of a nearby highway (I-93). Salty water flows into the lake via a drainage channel that received highway runoff. The study predicts that by 2025 the concentration of sodium will triple and the concentration of chloride will increase eight times over preroad construction concentrations. Steps are being taken to reduce the use of salt on the highway and to divert surface water flows away from the lake.

The effect of salt on plants and animals has been well documented and generally results in a reduction of species diversity and higher mortality rates. Plants have to work much harder to remove water and nutrients from salty water. This leads to browning or stunted growth. Conifers are one of the most sensitive species, showing signs of damage at salt (chloride) concentrations as low as 30 mg/L. Uptake of salty water lowers the resistance of native plants to disease and predation and opens ecological avenues for less desirable invasive species such as cattails or reeds. In freshwater bodies, algae growth and health, the basis of most ecosystems' food web, can be disrupted by salt concentration increases in the range of 10–15 mg/L. Fish, especially trout, are affected at 250-mg/L ranges, with a 50 percent mortality rate reported at around 6,500 mg/L. Behavioral abnormalities have been reported in birds that ingest only a few grams of salt, as a result of their inability to distinguish the salt particles from seeds. Unlike carnivores, which metabolize much of the salt they need from meat, large herbivores such as moose and deer often have salt-deficient diets. They are attracted to roadsides, where they drink salty water or lick halite recrystallized on pavements or nearby structures. This increases road kill rates, as well as the damage to motor vehicles.

The outdoor storage of large piles of road salt also can result in soil and groundwater contamination. One such example happened in the small town of Hefley, British Columbia, in Canada (population 700). The town stored an abrasive-salt mixture used for servicing a 25-mile (40-km) stretch of four-lane highway in two outdoor piles. The town's water supply is taken

from a series of nearby wells. In 1993, the local water utility began to receive complaints that the drinking water tasted salty. The subsequent investigation quickly led to the conclusion that the salt storage site had contaminated the groundwater supplying water to town residents. New wells were drilled and the top eight feet (2.5 m) of contaminated sand and gravel underlying the piles was removed. This material, some 5,700 cubic yards (4,350 m<sup>3</sup>), was crushed, combined with salt, and stockpiled for future use in road maintenance activities. The costs of the drilling of five new production wells and installation of new piping, pumps, and so on, was approximately \$1.2 million. The highway authority then constructed a salt storage building, which cost about half of the cleanup at \$600,000. It would have been far less expensive to construct a proper storage facility than to remediate salt-contaminated soil and groundwater after they were polluted.

Today, most state and local highway and related regulatory agencies recognize the environmental threats posed by outdoor, unprotected storage of road salts. These materials are now placed inside specially constructed igloos that have impervious concrete floors and internal drainage systems or salt traps, designed to prevent water that may leak from or have contact with the salt from entering surface water or groundwater. In addition, new salt application procedures are being implemented to reduce the amount of salt being spread and minimize its potential environmental impact. These include presalting roads before major snowstorms; applying the salt in liquid form, which allows it to interact with the ice and snow already on the roadway more efficiently and at lower temperatures; and even using computer-controlled spreaders that can sense the amount of ice or snow on a roadway and apply only that amount of salt needed to help remove it.

## ABRASIVES

Sometimes used in combination with salt or as a stand-alone ice/snow management agent, sand as an abrasive is also often spread onto roadways to improve traction. Sand (SiO<sub>2</sub>) typically is the material most commonly used, but some communities that have access to large quantities of either free or very-low-cost industrial by-products have made use of ground-up slag, mining residues, wood chips, fly ash, or bottom ash from coal burning, and other relatively inert materials as traction control aides. This practice, however, has largely fallen out of favor because of concerns related to both accident liability and possible environmental impacts.

To be effective, sand usually must be mixed with some salt to prevent it from freezing and to help ensure a good bond with ice and snow that may already be on the roadway. Sand that is angular provides better traction than rounded or smooth sand grains. The optimal size for traction control sand is large and ranges from medium sand (0.012 inch [0.3 mm]) to fine gravel (0.38 inch [9.5 mm]). Smaller particles actually create slicker surfaces, and larger sizes may result in damage to vehicles.

Chemically, abrasives do not pose much of an environmental hazard. They do not degrade or interact to form hazardous or ecologically damaging compounds. They can, however, increase turbidity and change sedimentation patterns in surface water bodies. This can lead to adverse habitat impacts for aquatic vegetation and insects as light levels and stream or lake depths are reduced. This, in turn, can affect fish feeding and migratory relationships, as well as subsequent ecological interactions with higher-order species. Abrasives tend to accumulate in catch basins and drainage pipes and need to be removed periodically. During dry periods, they can cause dusty conditions that reduce visibility and degrade local air quality. Many of the control procedures being used to improve management of potential environmental effects of salt applications are also employed for abrasives, including more precise application, improved storage, and upgraded sediment control and water conveyance systems.

### LIQUID DEICERS

Another class of cold weather management materials are liquid deicers. These include agricultural by-products from sugar and grain (corn) distillation. Corn, beets, and many other agricultural products undergo a steeping process, whereby the material is immersed in a solution of warm water to help hydrate and separate it. In the case of corn, this is done to remove the husk or other noncommercial components. This water, which now contains dissolved carbohydrates and other plant ingredients, can be used in animal feed products or processed into road deicing compound. Liquid deicers are mixed or applied in combination with salt or sand. They work at lower temperatures than halite and adhere better to most road surfaces, so less has to be applied. Liquid deicers commonly are used as "antiicers," applied before frost, ice, or snow accumulates and has a chance to adhere to the road surface. The use of a liquid deicer allows snow and ice to be removed more readily with plows and scrapers. The first antiicing application usually is done before the first ice or snow of the season begins, and

the product is reapplied as needed after plowing to reduce ice or snow bonding.

In the environment, liquid deicers are more biodegradable than salt or abrasives. These materials, however, can contain high concentrations of soluble organic carbon, as well as growth nutrients such as nitrogen and phosphorus. Since they are liquids, these deicers can more easily enter the ecosystem and increase both carbon and nutrient loading on surface water bodies. This may result in waterway eutrophication, which has significant impacts on local ecosystems. High levels of nitrogen in the groundwater, in excess of 10 mg/L, can render the groundwater nonpotable and, if the nitrogen-rich water is ingested by infants or young children, cause methemoglobinemia. Most state transportation agencies now specify the use of low-carbon and low-nutrient-content liquid deicers for use on roadways and airport runways.

An alternative to both salts and agriculturally derived liquid deicers is a class of alternative deicing agents, of which the primary one is calcium magnesium acetate, or CMA. This is a biodegradable, noncorrosive compound made up of limestone mixed with acetic acid. Depending upon the concentration being used, CMA can be an effective antiicing agent down to temperatures close to -22°F (-30°C). Once in the environment, CMA breaks down to calcium and magnesium, as well as acetate. The acetate, an organic compound, is quickly degraded by microorganisms present in soil and water as a carbon source. CMA works more slowly than salts and liquid deicers and is much more expensive, costing almost 20 times as much as an equivalent amount of salt. As it gains more widespread use, especially for roadways in ecologically sensitive areas such as national parks, CMA may become more cost-competitive.

The need to keep highways and airports free of ice and snow must be balanced with the environmental and infrastructure effects associated with the use of salts, abrasives, liquid deicers, and other snow and ice management agents. Transportation authorities have the difficult task of selecting and using snow and ice control techniques that work and are cost-effective, while minimizing effects on surface water, groundwater, and air quality. As is the case with many other human-environment interactions such as pest management, the best approach may be one that combines a variety of methods that evolve as deicing products and application technologies improve.

particulate (fly ash), polycyclic aromatic hydrocarbons (PAHs), benzene, NO<sub>x</sub>, SO<sub>x</sub>, CO, CO<sub>2</sub>, and many other vaporized pollutants such as mercury. There are numerous other point sources of air pollution that are not so obvious. These are chemical plants and other manufacturing plants that use organic chemicals. The pollutants are in vapor form from the evaporation of volatile organic compounds (VOCs) and are probably even more abundant in the atmosphere. Some air pollution can be in the form of particulate, blown by the wind off mine spoils, piles at manufacturing facilities, trains, and dump trucks in the form of dust. These can include heavy metals, asbestos, lime, phosphates and other fertilizers, sulfur and sulfides, and numerous other powders. There are also natural point sources of pollution such as volcanoes and forest fires.

### NONPOINT SOURCE POLLUTION

Nonpoint source pollution is generally not as ecologically devastating as point source pollution in the short term, but it affects far more people and is more likely to cause major and lasting damage to the environment and public health. It is in generally low concentrations that are unlikely to be a public health hazard individually or even collectively in most cases. The problem is that the sheer volume of pollutants released by many nonpoint sources is immense. A National Academy of Sciences report found that in North American coastal waters "the thousands of tiny releases, carried by streams and storm drains to the sea, are estimated to equal an Exxon Valdez spill—10.9 million gallons of petroleum—every eight months." These pollutants can cause major and perhaps irreparable damage to the environment on a regional to global scale. It is the nonpoint source pollution that is responsible for the most pressing of our environmental problems.

According to a study by the National Oceanic and Atmospheric Administration, nonpoint source pollution affects "the beauty and health of coastal lands and waters. If the physical environmental well being of these areas is diminished, people will naturally find it less appealing to visit the coast." This same study finds that U.S. coastal and marine waters support 28 million jobs and contribute more than \$30 billion to the domestic economy through domestic fishing alone.

Nonpoint source pollution has many small sources to which most humans contribute. Nonpoint source air pollution is primarily from automobile exhaust. It emits benzene, NO<sub>x</sub>, SO<sub>x</sub>, CO<sub>2</sub>, CO, particulate, and partially burned hydrocarbons, all of which are the main components of urban smog. All other engines produce the same products. There are many other nonpoint combustion sources including home and industrial furnaces, fireplaces, grills, and open fires. The main pollutants from these sources are PAHs, CO<sub>2</sub>, CO, and particulate, though they may vary depending upon composition. The CO<sub>2</sub> from nonpoint sources is the main culprit in global warming and the greenhouse effect. The NO<sub>x</sub> and SO<sub>x</sub> produce acid precipitation, which originates primarily in nonpoint sources. The other main classes of pollutants are vapors from volatile chemicals. Every time gasoline or other fuel is exposed to the air, a small part evaporates. This same process occurs with drying oil paint and finish, glues and other adhesives, solvents, sprays, photocopying, and many other everyday items. These VOCs react with the NO<sub>x</sub> in the atmosphere to produce tropospheric ozone, which is very damaging to plants.

Surface water is also greatly affected by pollutants from nonpoint sources. Urban and agricultural runoff is the main vehicle for pollution. In urban and suburban areas, there are numerous chemicals on the surface that are swept into surface water

bodies during storms and floods. Fallout from the rampant air pollution coats most surfaces. Lawns and gardens are sprayed with pesticides and fertilizers. Areas with septic systems risk overflow of raw sewage, especially during spring thaw and other wet periods. Roads contain numerous compounds ranging from road salt and other deicing compounds to spilled oil, gasoline, and antifreeze from the motor vehicles passing over. There are chemicals on houses, sidewalks, parking lots, and businesses, in addition to all of the litter that is common to these areas, all of which are washed in the runoff into sewers and, untreated, into surface water bodies. A study conducted by two researchers on Long Island, New York, found that “bacteria and other contaminants enter the South Shore bays, the Peconic bays, the Long Island Sound and other surface water in the runoff from heavy rains, when drains divert huge amounts of water from roads and parking lots.” All of this input produces eutrophication of these bodies. The washout of NO<sub>x</sub> and SO<sub>x</sub> also produces acid precipitation that can cause

a public health threat, degrade urban infrastructure, and destroy the ecology of sensitive lakes and ponds.

Agricultural nonpoint sources produce most large-scale damage to the environment. Fields are doused with fertilizer before the seeds are planted and sprayed with pesticides afterward. Both of these are used in excess to ensure maximal yield of the plants. During storms, the fertilizer is dissolved or carried as particles in surface runoff and deposited in lakes and rivers. This process causes eutrophication of the lakes; the rivers carry the excess nutrients to the oceans. If the marine input area is restricted as in a bay, gulf, sound, or sea, eutrophication also takes place, producing a dead zone. The water of these dead zones is oxygen deficient to the point where they cannot support any life beyond jellyfish. All fish and invertebrates either escape or die, destroying the productivity of these areas. Destruction of the food output from such a vast source as the ocean may have dire consequences for the human race.

**Block diagrams showing some common sources of pollution in which there is a single point source (A) that can be readily identified and there are diffuse nonpoint sources (B) that cannot be readily identified**

Pesticides are equally overused and damaging to human health and the environment. Although pesticides have saved millions of human lives by controlling disease-carrying insects and crop-destroying insects, they also produce collateral damage. In the 1960s and 1970s, tests showed that there was so much pesticide in human breast milk worldwide that it was dangerous to babies. In response, many persistent pesticides were banned in favor of more selective and potent, shorter-acting types. The problem with milk subsided, but there is now a crisis in honeybee populations in which pesticides are strongly suspected. The crisis is called colony collapse disorder (CCD); in it whole hives simply perish all at once. It is especially prevalent in North America, where nearly one-third of the already greatly diminished population of honeybees disappeared in 2007. The problem is that the vast majority of the pollination of flowers is done by honeybees. Without them our supply of all fruits and nuts and most vegetables is in jeopardy.

These agricultural and home use pesticides and fertilizers also leach into the groundwater system. Residues are found in well water throughout the United States. The problem is especially acute in coastal areas, where all drinking water must be taken from the shallow aquifer because the deeper water is saline. Any fertilizer or pesticide applied to the surface quickly leaches through the sandy soil that characterizes these areas and enters the groundwater system. This reliance on this commonly contaminated shallow groundwater in these areas may be the reason for the elevated incidence of cancer.

There are also natural nonpoint sources of pollution. Soils and rocks in an area can contain elevated levels of dangerous inorganic pollutants. Arsenic is the most widespread and perhaps the most common of these dangerous pollutants. The worst case of natural arsenic poisoning is in Bangladesh, where tens of millions of people suffer its effects. In some cases, it is the interaction of anthropogenic pollutants with the natural sources that causes the problems. Some agricultural fertilizer can strip naturally occurring mercury from clay deposits and release it into the groundwater system. Other less dangerous chemicals such as sulfur are widespread in groundwater and degrade the quality. Sulfur also lowers the pH of the water, with the potential to dissolve copper and lead from the plumbing system, further degrading the water quality.

**Pollution Abatement Services Oswego, New York (1977–present)** *SoilandGroundwater Pollution* By the 1960s, the water quality in Lake Ontario had deteriorated to the point where it was on the verge of ceasing to be a viable ecosystem. Phosphate-rich sewage, primarily from household detergents, poured into the lake, causing enormous algae blooms that drastically lowered the water's oxygen content and killed thousands of fish. Runoff from farms that contained high concentrations of agricultural chemicals such as pesticides, herbicides,

and fertilizers combined with untreated industrial wastewater to add a toxic component to the already degraded water. By the early 1970s, conditions had worsened to the dangerous level, and both the American and Canadian governments were forced to act. Sewage treatment plants were upgraded, and phosphates were banned from laundry detergents. An intensive education and outreach program to local farmers was successful in reducing the amounts of agricultural chemicals used and in improving the quality of surface water runoff into the lake. Finally, industrial sources of lake pollution began to receive scrutiny. One of the first to merit close attention was Pollution Abatement Services, a 15-acre (6-ha) site in Oswego, New York.

### BACKGROUND

Oswego is a small town of about 18,000 inhabitants on the shore of Lake Ontario. This part of western New York holds the distinction of receiving some of the heaviest snowfalls in the lower 48 states. During winter, the wind picks up moisture as it blows across the lake and dumps it on Oswego, Syracuse, and other nearby cities. Often as much as 20 feet (6.1 m) of snow per season falls in this part of the country. Around 1902, a local resident tried to capitalize on the water and freezing temperatures. He installed a concrete dam along the northwestern corner of a 15-acre (6-ha) tract about two miles (3.2 km) east of downtown Oswego and the Oswego Canal and only 1,800 feet (550 m) south of the lake itself. This small parcel was surrounded on its east, north, and west sides by White Creek and Wine Creek, as well as wetlands. These streams flow northward from upland farms and pass through the area on the way to Lake Ontario. Damming up the streams allowed the winter ice to be harvested and stored for sale in the nearby growing town of Oswego or even barged by canal to Syracuse. The business, however, foundered as electricity and refrigerators became more commonplace, and Oswego County eventually took ownership of the property because of unpaid taxes.

### POLLUTION OF THE SITE

Undeveloped for many years, the site began to be used as a landfill during the 1950s, receiving rubble and demolition debris as the post-World War II construction boom swept across western New York. Looking toward more sustainable regional development, Oswego County and the Port of Oswego Authority (Port Authority) turned over the site to a group of local businessmen for the construction and operation of a high-temperature liquid chemical

waste incinerator. This operation became known as Pollution Abatement Services, or PAS.

PAS began operating in late 1969 and, at its peak of operation, employed some two dozen local residents. The facility received liquid wastes in tanker trucks and drums, classified their contents, and incinerated the material for a fee. Operating under permits from both Oswego County and the state of New York, the business prospered. The chemical industry was very active in this area, and PAS was providing a much-needed waste management service. Throughout the 1970s, as environmental regulations became stricter and competition from other waste disposal sites increased, residents began to complain about the stacks of drums and strange smells emanating from the site. A series of events that began in 1973 attracted the attention of regulatory agencies to PAS's increasingly shoddy operations.

PAS was not a large site. To increase the liquid storage capacity, operators constructed three lagoons, or retention basins, on the property. They also installed numerous aboveground and underground storage tanks. Even with this increased capacity, PAS accepted liquid waste material faster than it could safely incinerate or even store it. The lagoons regularly overflowed, with chemical wastes entering a drainage ditch directly down the center of the site and discharging into White Creek. A few hundred yards downstream, White Creek combines with Wine Creek and this combined flow empties into Lake Ontario.

The area around PAS was fairly rural during the facility's operational life. Some private residences were to the north of the site, but land use was primarily undeveloped woodland. A few dozen homes are clustered about a half-mile (0.8 km) north of PAS, on the shore of Lake Ontario in an area known as Smith's Beach. A union hall was to the east, and a radio station had its offices on the west. The Oswego County landfill was to the south of the PAS site. The local environmental and public health impacts from PAS were not insignificant, but the real threat posed by the site was in the area where White and Wine Creeks enter Lake Ontario. It is about one mile (1.6 km) from the drinking water intakes for the city of Oswego. Chemicals from the PAS site that overflowed into surface streams made their way to Lake Ontario and possibly into Oswego's water system. In addition, the White and Wine Creek stream system, although biologically stressed by impacts from PAS and other contaminant sources, supports numerous bird and aquatic species. The streams also are spawning grounds for a number of fish species and, near Lake Ontario, are used for recreational fishing.

Between 1973 and 1977, PAS was cited for numerous violations of its permits and for illegal discharges into the air and surface water. In 1977, the site was abandoned, and its employees and owners simply stopped showing up for work. They left on-site more than a million gallons (3.8 million L) of oil and mixed chlorinated and nonchlorinated hydrocarbons and more than 15,000 leaking and deteriorating drums full of chemical wastes. Faced with a large and expensive cleanup, the New York Department of Environmental Conservation (DEC) and the U.S. Environmental Protection Agency (EPA) turned to the Clean Water Act for funding to clean up the site. Although these federal funds were originally intended to build municipal sewage treatment plants, the situation at Oswego was considered so dire that the rules were stretched to provide some initial financial support.

### THE CLEANUP

A dike was quickly constructed around one of the lagoons to prevent it from overflowing. Next, the dangerous liquids were removed from the lagoons, the contaminated sludge scraped out, and the open hole backfilled with clean soil. More than 80,000 gallons (302,400 L) of liquid waste had to be drained from the storage tanks, and then these tanks had to be cleaned and torn down. More than 15,000 drums were still present on the site, many of them requiring overpacking, a procedure in which a rusting or damaged 55-gallon (208-L) drum is placed carefully inside an 85-gallon (321.3-L) drum so it can be shipped safely to an off-site disposal facility. By 1980, both EPA and NYSDEC realized that the work needed to stabilize and secure PAS from a fire, spill, or other sort of catastrophic event far exceeded the available funds, and work slowly came to a halt.

With Clean Water Act funding almost exhausted, the EPA nominated PAS for inclusion on the newly formed National Priorities List. In 1981, the site was placed on the list, with a final ranking of number 8, and federal Superfund monies now became available to address the remaining site stabilization issues. By 1984, the majority of the wastes had been removed from the PAS property, but soil and groundwater quality had not yet been investigated, and the impacts of past releases on local ecology including White and Wine Creek stream sediments, were still unknown. In addition, severely contaminated soil and black oily leachate were present near the former tanks and could be a source of continuing surface water and groundwater contamination.

Prior to the selection of a remedial solution, a feasibility study (FS) is conducted. The EPA's stated

goal for the FS is to identify and evaluate remedial alternatives and select one that is the "lowest cost alternative that is technologically feasible and reliable and which effectively mitigates and minimizes damage to and provides adequate protection of public health, welfare, or the environment."

During site stabilization activities, a wide variety of contaminants were identified, including waste acids and alkalis, polychlorinated biphenyl (PCB)-contaminated solids and liquids, halogenated organics, organic resins, and heavy metal-laden wastewater. These compounds are toxic and/or carcinogenic and represent a significant risk to worker safety, public health, and the local ecology. To evaluate the extent of soil and groundwater contamination, samples were taken across the 15-acre (6-ha) site. Findings suggested that soil contamination was significant, often approaching saturation values, but was widespread and nonuniform. This type of distribution pattern indicated that there had been multiple contaminant sources on the property.

The groundwater was in better condition. Soft shale and limestone bedrock in the area had been scraped out by glacial action during the last ice age and pulverized into a fine clay or a mix of densely compacted sand, silt, and clay and deposited around Oswego, including at the PAS site. Underlying a thin layer of demolition debris that had been laid down across the site when it was a landfill, there is a 10-foot- (3.1-m-) thick layer of a glacially derived dense, low-permeability ( $2.5 \times 10^{-5}$  inch/s [ $5.5 \times 10^{-5}$  cm/s]) lodgment till. This till acts as an effective hydraulic barrier to the downward migration of contaminants into the underlying moderately fractured sandstone bedrock.

Although groundwater within the till is contaminated, especially in areas where most of the waste was stored such as the aboveground tanks and lagoons, this shallow water is not used regionally as a source of potable water. The risk that this shallow impacted groundwater poses is that it discharges as surface seeps and springs into the channels of White and Wine Creeks, which flow into Lake Ontario and discharge near the water intake for Oswego. In fact, groundwater contamination was found in only one monitoring well in the upper part of the fractured sandstone bedrock, and that was linked to poor drilling practices. It was determined that the seal around the monitoring well casing was not installed properly and that shallow groundwater was trickling down the length of the well and entering the underlying bedrock aquifer. Once that well was removed and the borehole sealed, further contamination in the fractured sandstone was not detected. The presence of the lodgment till also

allowed the development and implementation of an effective remedy to control migration of shallow groundwater off the PAS property and into White and Wine Creeks.

A slurry wall, also called a diaphragm wall, or cut-off wall, is a subsurface barrier consisting of vertically excavated trenches filled with a clay slurry, a soupy mixture of water and fine sediment. The slurry is usually a combination of bentonite (a type of clay that expands when wet), Portland cement, coal ash, and water. It is poured into the trench to prevent the walls from collapsing during excavation, but it also greatly reduces or even eliminates the flow of groundwater through it. As the trench is deepened and connected to a less permeable subsurface layer or even bedrock, if it has the right characteristics, the excavated soil is mixed with more bentonite and returned to the trench, where it hardens. Essentially, it creates an underground dam. As added protection, a layer of plastic can be draped across the downgradient side of the trench to slow groundwater flow further and prevent the migration of vapors that may be emanating from the contaminated groundwater. Slurry walls can be installed at depths as great as 100 feet (30 m) and are generally two to four feet (0.6–1.2 m) thick.

At the PAS site, a slurry wall was constructed around the most contaminated areas to the base of the lodgment till. Collection sumps were installed inside the wall, where groundwater is periodically recovered by using a vacuum hose, literally sucking it into a tanker truck. This recovered groundwater is then driven to an authorized disposal facility for processing and eventual discharge. Approximately 400,000 gallons (1.51 million L) per year of recovered groundwater is managed in this way, and this process, coupled with an extensive groundwater monitoring program, is likely to continue for the foreseeable future.

### THE AFTERMATH

While this work was ongoing, the EPA and NYSDEC reviewed PAS's business records and identified almost 100 companies that paid PAS to accept and process their wastes. These 100 companies, called "potentially responsible parties," were notified that they must reimburse the EPA for the cleanup activities it had undertaken at PAS. If they refused, the EPA would have filed a cost recovery action in federal court under its CERCLA "joint and several liability" authority. After tough negotiations, they agreed, and most of the funding for the cleanup was shifted from Superfund to the group of potentially responsible parties.

Further studies by EPA, NYSDEC, and the potentially responsible parties concluded that concentrations of contaminants in the soil decreased with depth, with almost all of the volatile organic compounds and PCBs present within the upper 10 feet (3.1 m). Remedial engineers concluded that this contamination was best addressed by removing the most highly contaminated soil and capping the remainder of the site with a clay layer in order to reduce the likelihood of human exposure and to help isolate it from the environment. A supplemental study concluded that the PAS site was not the source of pesticides in the surface water of Wine Creek and is not presently a source of PCB contamination in the sediments in the adjacent wetlands or the creeks. PAS was a likely source of PCB contamination before remedial activities had been completed. This same study identified two other likely PCB sources in the vicinity of PAS.

The PCBs found in White and Wine Creek sediments were determined not to pose a serious enough risk to local flora and fauna to justify the habitat destruction associated with their excavation and removal. Groundwater in the bedrock was not contaminated, but, as a precaution, the Oswego municipal water supply system was extended to the area, and nearby users were given the opportunity to connect to it. Many declined, preferring to continue to use private wells. A review of the effectiveness of the remedial action at PAS, conducted every five years by EPA, concluded that the cleanup activities implemented and ongoing at the site were fully protective of human health and the environment. The EPA further found that, under current conditions, potential or actual human exposures are under control.

Thanks to the cleanup of PAS and other sites like it, as well as the more regionally implemented water quality initiatives such as the banning of phosphate detergents and the upgrading of sewage treatment plants, the majority of Lake Ontario is now a thriving sports fishery and an important recreational center for both Canadians and Americans. Its pristine beaches are popular tourist destinations, and introduced coho and chinook salmon are flourishing. While in places lake sediments still contain troubling levels of mercury, PCBs, and other industrial contaminants and invasive species such as the zebra mussel still pose problems, progress has been made and Lake Ontario once again stands out as one of the most outstanding natural resources in North America.

**Poza Rica disaster Poza Rica, Mexico (November 24, 1950) Air Pollution**

Hydrogen sulfide ( $\text{H}_2\text{S}$ ), also called swamp gas or sewer gas, is a dangerous asphyxiant. Colorless, highly flammable, and explosive, hydrogen sulfide is heavier than air and often accumulates in enclosed, low-lying, or poorly ventilated areas. Although it has a very disagreeable smell of rotten eggs at concentrations as low as 0.5 part per billion (ppb) warning of its presence, it also acts as an olfactory deadening agent. As exposure duration increases, the hydrogen sulfide numbs or paralyzes the sense of smell, usually within a few minutes, leading the exposed individual to the false conclusion that the gas has dissipated. Rather, as is most often the case in industrial accidents, the  $\text{H}_2\text{S}$  gradually displaces the air and causes the deaths of workers and rescuers alike.

Once inhaled, hydrogen sulfide decreases the oxygen-carrying capacity of blood. The toxic effects are similar to those of hydrogen cyanide: The central nervous system slows as the lack of oxygen shuts down cellular respiration. Loss of consciousness occurs, and, without prompt medical treatment, death quickly follows. Low concentrations (<300 parts per million [ppm]) of hydrogen sulfide do not cause an immediate toxic response, but fatigue, loss of appetite, and headaches can result from long periods of low-level exposure. These symptoms diminish

within weeks after exposure ceases. Concentrations of 700–800 ppm are usually fatal within five minutes. At 1,000+ ppm, the majority of exposed individuals collapse immediately, after inhaling just one breath. Typical, naturally occurring  $\text{H}_2\text{S}$  concentrations in air range from 0.0001 ppm to 0.0002 ppm. The U.S. Environmental Protection Agency (EPA) has set a safe exposure level for hydrogen sulfide at 0.0014 ppm.

$\text{H}_2\text{S}$  can be released directly into the air from volcanoes and hot springs through the hydrolysis of sulfide-containing minerals such as pyrite ( $\text{FeS}_2$ ). In fact, about 90 percent of the hydrogen sulfide in the atmosphere is attributable to natural sources. It can also be produced by sulfate-reducing bacteria in stagnant-water, oxygen-poor settings, such as swamps or bogs.

The most important industrial sources of hydrogen sulfide are petroleum and natural gas extraction and refining. Certain types of textile production and pulp, paper, and chemical manufacturing, as well as municipal waste disposal, also produce hydrogen sulfide gas. It can be mixed or dissolved in both oil and natural gas, and concentrations range from a few parts per million to as much as 30 percent. Besides being a health hazard and an air pollutant, hydrogen sulfide causes corrosion and metal fatigue. As a weak acid,  $\text{H}_2\text{S}$  in the water or moisture of oil or natural gas enhances the absorption of hydrogen by steel. As the  $\text{H}_2$  penetrates the metal vessels and pipes of the refinery, the steel becomes brittle and loses its flexibility and strength. Eventually, it blisters, cracks, or simply breaks apart. In some cases, iron sulfides form and plug pipes and foul valves. Refineries deal with this problem by removing the  $\text{H}_2\text{S}$  from the hydrocarbon fuel and converting it to elemental sulfur. The hydrogen is burned along with other waste gases in a flare, while the sulfur is collected and often distributed commercially. Recently, some refineries have been experimenting with ways to collect the excess hydrogen and sell it as an alternative fuel source.

**BACKGROUND**

On Mexico's Gulf Coast, 20 miles (32.2 km) west of Tuxpan and 140 miles (225.3 km) northeast of Mexico City, the small town of Poza Rica (1950 population of 22,000) hosts a thriving oil and gas refining industry. Built on the floodplain of the Rio Cazones, Poza Rica is surrounded by hills rising about 330 feet (100.6 km) above the floor of the valley. Its climate is subtropical, with temperatures rarely dropping below 60°F (15.6°C). Most of the houses were

constructed of split bamboo, with large windows and doors to ensure maximal airflow. Many rested on platforms a few feet off the ground to allow as much air exchange as possible.

The refineries and associated sulfur recovery plants in 1950s Poza Rica were operated by Petroleos Mexicanos (Pemex), the government-run oil company. They were built to exploit the extensive deposits of oil and natural gas found in this part of Mexico. In November 1950, as production activities were being expanded, a new sulfur recovery plant was opened to remove hydrogen sulfide from the natural gas being processed at a nearby refinery. This gas contained about 3 percent (or 30,000 ppm) hydrogen sulfide. The sulfur recovery plant was divided into two units, with each unit able to process 60,000,000 cubic feet (1,699,011 m<sup>3</sup>) per day of natural gas. The final step in the process, when the concentrated hydrogen sulfide gas (16 percent or 160,000 ppm) was to be sent to a reactor to recover the sulfur, had not been constructed. Instead, the H<sub>2</sub>S was diverted to a tower, where it was mixed with low-sulfur methane and ignited in a flare that would reach heights of up to 30 feet (9.1 m).

### THE INDUSTRIAL ACCIDENT

Operational problems plagued the gas flare from the beginning. Amine solution, used to help remove the hydrogen sulfide from the natural gas, periodically overflowed and extinguished the pilot light of the flare or clogged its methane gas supply lines. Flow rates were reduced to 40,000,000 cubic feet (1,132,674 m<sup>3</sup>) per day, and this seemed to work for a while, but pressure on production staff to increase plant output was intense. At 2:00 A.M. on November 24, 1950, the facility's operator succumbed to this pressure and ordered flow rates to be increased to the maximal output of 60,000,000 cubic feet (1,699,011 m<sup>3</sup>) per day. For about 90 minutes, the process seemed to be working fine, but at 3:30 A.M., the strip chart recorders began to show that gas flow to the flare was erratic.

At 4:40 A.M., the shift supervisor implemented emergency shutdown procedures, but by then gas had begun to infiltrate the village. Later investigations found that the amine scrubber solution had overflowed and extinguished the flare's pilot light. For 20 minutes, between 4:50 A.M. and 5:10 A.M., 800,000 cubic feet (23,305 m<sup>3</sup>) of gas containing

Flare system at Pemex oil field in Poza Rica, Veracruz, Mexico, burning excess hydrogen and other waste gases © Sergio Dorantes/CORBIS

high concentrations of hydrogen sulfide escaped from the inoperative flare vent. At the time, a late fall temperature inversion in Poza Rica had produced a rare cool evening, with air temperatures in the low 60s°F (ca. 15°C) and a thin mist filling the valley. This inversion also reduced atmospheric mixing and forced the hydrogen sulfide gas to move laterally with the developing morning breeze, where it settled over a nearby residential neighborhood. Exposure concentrations were subsequently calculated at 1,000–2,000 ppm H<sub>2</sub>S.

In one home, only 400 feet (121.9 m) from the sulfur recovery unit, a father, awakened by the characteristic “rotten egg” smell of H<sub>2</sub>S, managed to snatch his infant daughter from her crib and stumble down the street before collapsing. Although he and the four-month-old baby survived, his wife and three other children died that night in their sleep. Townspeople formed makeshift rescue squads, dragging apparently lifeless residents from their homes and taking them by cab or truck to the hospital. Racing to the facility, the plant superintendent saw the bodies of employees and residents lying either dead or unconscious in the street. In all, 22 people perished from hydrogen sulfide exposure, and 320 were hospitalized. More than 50 percent of the pets and domestic livestock in the neighborhood were also killed. A mass funeral service was held a few days later for the victims, and the sulfur recovery plant was put back online.

### THE AFTERMATH

Today, Poza Rica is still the center of Mexico’s oil and gas industry. It is also trying to define itself both as a tourist destination and as a broad-based commercial and transportation center. The majority of its 500,000 residents probably do not notice the small black or gray boxes that contain H<sub>2</sub>S detectors that have been mounted on poles around the town in case there is another disaster.

**Prestige oil spill Galicia, Spain (November 13–19, 2002) Water Pollution** Spain is one of the most decentralized countries in Europe, containing 17 autonomous communities and two autonomous cities, which are subdivided into 50 provinces. Each of these autonomous areas has a wide degree of freedom to manage its own internal political and social programs such as health care, education, and security. Galicia, on the Iberian Peninsula along the west coast of Spain, is one of these autonomous areas. Bounded by Cape Fisterra, Galicia is the westernmost point of continental Europe, and its rugged coastline is known by mariners around the world as the Costa del Morte, or coast of death. The jagged cliffs that reach to the edge of the sea and beyond combined with fierce shoreward winds and strong currents have resulted in an average of three shipwrecks per year for the last 100 years.

### BACKGROUND

In addition to its dangerous maritime reputation, the coastline of Galicia is well known as one of the most scenic areas in Europe. Tourism is an important component of the region’s economy, and people travel from all over Europe to enjoy the lush green hills and valleys and rocky, isolated coves and bays on the coast. These same coves and bays provide important wintering habitat for seabirds from throughout the North Atlantic including gannets, guillemots, cormorants, puffins, and gulls. Galicia’s offshore waters are well oxygenated and nutrient rich and support an abundant variety of fish, shellfish, whales, dolphins, and porpoises. The Galician fishing fleet, composed mainly of small family-owned and operated vessels, is the largest in Europe, and many local residents make a living by gathering and selling shellfish.

After a structural failure, the oil tanker *Prestige* leaves a trail of oil near Muxia, Spain, November 13, 2002 (AP Images)

Galicia also is on one of the world's oldest and most important shipping lanes. Supertankers full of oil and other types of merchant vessels sailing from the Persian Gulf, India, and China make their way northward along the west coast of Africa and sail directly past Galicia on their way to ports in mainland Europe. Similarly, southbound ships skirting the coastline of Europe make their way past Galicia loaded with North Sea oil or goods from Western Europe as they sail westward toward the Americas. It was this type of voyage that the *Prestige* had been making uneventfully for most of its 26-year life, until early November 2002.

Launched in 1976, the tanker *Prestige* carried a crew of 27, was about 800 feet (243.8 m) long, and had a capacity of almost 23 million gallons (85,000 tons [77,000 metric tons]) of oil. It was an aging single-hull vessel that had undergone major repairs in a Chinese shipyard in 1991, having a number of cracks repaired in the hull. The tanker was loaded with heavy fuel oil (No. 6 or Bunker C) in the Latvian port of Riga and was bound for Singapore, around the Cape of Good Hope at the southern tip of Africa, after a brief stopover in Gibraltar. The *Prestige* was under the command of a Greek captain

with a mostly Filipino crew. At the time of the incident, the tanker was owned by a Liberian company, but on charter to a Russian oil business headquartered in Switzerland. The oil was the property of an English corporation, and the *Prestige* was registered in the Bahamas.

### THE OIL SPILL

While steaming south in either Portuguese or Spanish waters on November 13, 2002, the starboard side of the *Prestige* struck a partially submerged object. One crewman thought it might have been a derelict cargo container. Regardless of what the object was, it ripped a 150-foot- (45.7-m-) long gash through the hull of the ship, which began listing and leaking oil almost immediately. The captain radioed for assistance and turned toward the Spanish coast. Fearing that the *Prestige* would break apart and release its entire cargo onto the beaches of Galicia, Spanish coastal authorities ordered the vessel to turn around and head northwest, back to open ocean.

The captain changed course as ordered and steered toward France, but once again the *Prestige* was denied safe haven and ordered back to sea. Becoming desper-

ate and fearing for the lives of his crew, the captain turned toward Portugal, but the Portuguese navy was ordered to intercept the vessel and keep it away from that country's coastline. Now under tow by as many as five oceangoing tugs, the hull was becoming unstable, a condition not helped by the constant course changes and the deteriorating weather.

The captain requested that the crew be taken off the ship while he remained onboard with two volunteer crewmen to help with salvage operations. He pleaded with French, Spanish, and Portuguese shipping authorities to allow the *Prestige* to dock and off-load its cargo while there was still time. Concerned that a major catastrophe would occur if the ship were allowed into harbor, each country refused. With 20-foot (6.1-m) waves crashing over the damaged vessel, fighting winds of 50 miles (80.5 km) per hour, and still leaking oil, the *Prestige* was rapidly towed out to sea as far from the European mainland as possible. Finally, early in the morning of November 19, a 40-foot (12.2-m) section of the starboard hull peeled off, and, shortly after 8:00 A.M., the ship split in half. Later studies indicate that the hull failure may have occurred along one of the repair welds. The stern section quickly sank, while the bow floated for a few hours and eventually slipped beneath the surface in the early afternoon.

The *Prestige* sank in 12,000 feet (3.7 km) of water about 130 miles (208 km) off the coast of Galicia, releasing an estimated 18 million gallons (68 million L) of heavy oil. During the frantic, wandering search for a harbor and sinking, the *Prestige* created a slick 200 miles (322 km) long and five miles (8.1 km) wide that the winds and ocean currents moved quickly toward the Spanish, Portuguese, and French coastlines.

Since the 1970s, five of the 11 major oil spills in Europe have affected the Costa del Morte, but even for this much environmentally abused area, the *Prestige* spill was damaging. The oil went ashore in three distinct episodes. The first occurred on November 16, even before the *Prestige* sank, and the quantity of oil and its widespread distribution quickly overwhelmed initial cleanup efforts on the beaches. The second and largest slick arrived on November 20, the day after the *Prestige* sank, and the third "black wave," as the local residents called it, arrived on December 19, one month to the day after the *Prestige*'s sinking.

### THE CLEANUP

Although beaches in France and Portugal also were covered by oil, Galicia bore the brunt of the damage. Health authorities closed more than 1,000 miles

(1,609 km) of shoreline along both the northern and western coastlines of Spain. Intensive shoreline cleanup and ecological restoration attempts continued well into summer 2003, with thousands of volunteers, military personnel, and paid professionals collecting almost 110,000 tons (100,000 metric tons) of oil-contaminated materials from the Spanish shoreline.

The *Prestige* took almost 3.3 million gallons (12.5 million L) with it to the bottom of the ocean, and early Spanish claims that the heavy oil would congeal and not pose an ecological threat were quickly dismissed as the tanker continued to leak oil at an estimated rate of 30,000 gallons (113,562 L) per day. Temporary repairs by a French submarine a few months after the sinking slowed the leak rate to less than 200 gallons (757 L) per day. Finally, in summer 2004, a sophisticated remotely operated deep-sea robot sealed the cracks in the sunken stern and reportedly pumped most of the remaining oil into special aluminum canisters that were floated to the surface. Cleanup was not declared complete until December 2004.

### THE AFTERMATH

No fatalities were reported during the salvage and recovery efforts, but an estimated 15,000 birds died, and some nongovernmental agencies put the total number killed much higher at more than 100,000. The fishing and shellfish industry, on which some 80 communities along the Galician coastline depended, was destroyed, losing a combined \$70 million. It took more than two years to recover to prespill levels, but given the large amount of oil released, some experts have predicted that marine life could be impacted by the *Prestige* spill for as long as 10 years. This is because the hydrocarbons contained in the oil are capable of poisoning plankton, fish eggs, and crustaceans and may cause cancer in fish and other marine species.

Similarly, tourism dropped dramatically as beachgoers and bird-watchers sought less polluted places to spend their almost \$30 million vacation dollars. The captain of the *Prestige* was arrested and charged with hindering salvage attempts and creating a release to the environment but was not prosecuted. He was later sued, along with the owner and operators of the *Prestige*, for \$60 million of cleanup costs and for compensation to local fishermen. Some estimates of *Prestige*-related cleanup and compensation costs put the figure as high as \$2.8 billion, only about \$300 million of which was covered by insurance or civil liability compensation funding. The rest was paid by Spanish taxpayers.

Oil with chemical characteristics similar to that carried by the *Prestige* still washes up periodically on the Galician coastline, and the controversy over the *Prestige* was rekindled when a 2006 study by a group of Spanish researchers concluded that not all the oil had been removed from the wreck. Using an analysis of fresh, undegraded oil found floating near where the *Prestige* went down, as well as remote sensing techniques, they concluded that as much as 6.8 million gallons (26 million L) of oil could still be present within the sealed hull of the stern. They further concluded that bacteria are slowly eating through the hull and that a major release of oil is inevitable. Although the Spanish government and the contractor that performed the work discounted these findings, they continue to monitor the wreck.

**Price's Pit Pleasantville, New Jersey (1981–2011)** *Soil and Water Pollution* In 1968, the 26-acre (10.4-ha) sand and gravel quarry owned by Charles Price closed. The quarry stretched across the boundaries of Egg Harbor Township and the town of Pleasantville, New Jersey, about five miles (8 km) east of Atlantic City. It had operated for only two years and its sand and gravel resources had been quickly exhausted. When local residents began to use the pit as an informal garbage dump, Mr. Price seized the opportunity to increase the earnings from the property. In 1970, he applied for and received permission from the recently formed New Jersey Department of Environmental Protection (NJDEP) to operate a sanitary landfill, which eventually became known as Price's Pit.

#### POLLUTION OF THE SOIL

Shortly after opening as a landfill for household trash and construction debris, Price's Pit began to accept chemical wastes for disposal. This was done in spite of the specific restriction on the landfill's operating certificate prohibiting the receipt of "Chemicals (Liquid or Solid)." It was not until 1972 that Price's Pit operators officially requested permission from NJDEP to accept chemical waste. The NJDEP cautiously approved this request with the condition that "no liquid or soluble industrial wastes, petrochemicals, waste oils, sewage sludge, or septic tank wastes shall be received for disposal at the site." This list is so comprehensive that it virtually excludes all types of chemical or industrial wastes. By the time this permit modification was issued, Price's Pit had accepted an estimated 9 million gallons (34 million L) of chemical waste for disposal. These wastes were haphazardly dumped on the ground, often poured directly from tanker trucks onto the quarry floor with no attempt at treatment. In other cases, drums of dangerous chemicals were tossed onto the ground and then covered with trash. There are even rumors of late-night dumping activities and abandonment of entire tanker trucks in the pit because the contents were too dangerous to unload.

After an NJDEP inspection in November 1972, Price's Pit operators apparently stopped accepting chemical waste. The pit continued operating as a "sanitary" landfill until 1976, when waste disposal operations ceased. The site was covered with a few inches of sand, the gate across the access road was locked, and the operators left behind one of the largest repositories of buried chemical wastes in the United States.

When it rained or snowed, precipitation infiltrated the thin layer of sand covering the top of Price's Pit and percolated through the waste, rusting or degrading the containers and liberating their contents. Once mobilized, the mix of dissolved contaminants began to move eastward, carried along by the flow of groundwater. The stage was set for a true environmental disaster because about 90 percent of nearby Atlantic City's drinking water is taken from groundwater sources.

The Kirkwood-Cohansey Aquifer, a clean, well-sorted sand that extends under most of the coastal plain of southern New Jersey, including Price's Pit, is Atlantic City's main source of drinking water. Atlantic City pumps approximately 10–15 million gallons (38–57 million L) per day from the aquifer to meet the needs of its citizens and the casino atriums and reflecting pools. Of the 10 wells that make up Atlantic City's public well field, four are between the city

and Price's Pit. As the contaminants migrated away from the pit, a plume formed.

A plume is an underground distribution of contaminated groundwater created when contaminant spreads laterally in the same direction of groundwater flow. The site of original contamination, or the source of the plume, has the highest concentration of contaminant, which decreases as it moves away from the source. As the Price's Pit plume expanded, it put at risk almost half of the drinking water supply for 40,000 people. In addition, 35 private homes along the northeast border of the pit relied on groundwater from shallow wells as their only source of potable water. Many of these wells withdrew water that intersected the contaminant plume and residents noted drastic changes in their water quality shortly after the pit began accepting chemical wastes. Trees began dying and local residents reported that their skin burned after taking a shower.

This process of dissolution and migration of contaminants by infiltrating precipitation is called leaching. It happens at landfills, burial pits, or anywhere that wastes are exposed to precipitation and infiltration. The amount and rate of leaching are determined by a series of complex processes that are dependent on a variety of factors, including the type of waste, local climate, and site hydrogeology. Five of these processes are directly related to the makeup of the soil: porosity, permeability, cation exchange capacity, pH, and organic carbon content. At Price's Pit, the soil is porous and permeable and has a low cation exchange capacity and low organic carbon content. All these factors contributed to the quick generation and migration of chemically contaminated leachate. It was only through some truly remarkable action by the U.S. Environmental Protection Agency (EPA) and NJDEP that a major environmental crisis was averted.

### REMEDIATION OF THE SITE

The movement of contaminants toward the Atlantic City well field, which was a little more than a half-mile (0.8 km) east of Price's Pit, was discovered when people living close to the landfill began to complain about their well water. The Atlantic County Health Department (ACHD) collected some samples, expecting to advise the homeowners to have their septic systems repaired or change water softeners. Instead, they found drinking water with organic solvents and heavy metals at concentrations in the hundreds of parts per million. Realizing that they were on the brink of a major public health crisis, the ACHD notified EPA and NJDEP and asked for help.

Acting quickly, both regulatory agencies implemented a series of short-term remedial actions. The threatened Atlantic City wells were either shut down, redrilled deeper, or fitted with water treatment systems. Bottled water was provided to local residents until the city mains could be extended to the affected areas and the homes connected to them. Price's Pit was identified as the likely source of the contamination, and, in October 1981, it was placed on the National Priorities List as a Superfund site, so that funding could be made available for further action. The EPA, NJDEP, and Atlantic County eventually reached an agreement with 50 companies that had sent waste to this permitted and licensed facility to pay for the majority of the \$17-million cleanup.

As hydrogeologic conditions were determined at the site, EPA and NJDEP designed a long-term remedial solution. This plan included the installation of an 80-foot- (24.4-m-) deep slurry or containment wall that encircled the waste disposal area and controlled the lateral migration of contaminants. A series of groundwater extraction wells were installed east of the landfill and screened in the upper and lower parts of the aquifer. These wells are withdrawing water at the rate of approximately 200,000 gallons per day (756,000 L) and control the migration of the contaminant plume from the landfill. For 30 years, recovered groundwater has been treated through a treatment plant and returned to the landfill. The effectiveness of this groundwater pump-and-treat system is evaluated by regular monitoring of homeowner and sentinel monitoring wells. Eventually, the landfill will be capped with a combination of plastic sheets and clay to reduce the amount of surface infiltration. On-site treatment includes pH adjustment by addition of lime, air stripping to remove volatile organic compounds (VOCs), off-gas treatment with a dehumidifier and vapor-phase carbon adsorption, and final polishing with a sand and granular activated carbon filter. However, the effluent still contains high concentrations of heavy metals and is piped to the Atlantic County sewage plant for further treatment, prior to final discharge into the environment.

**primary air pollutants** Those pollutants that enter the atmosphere directly from a smokestack, tailpipe, chimney, evaporation, or the like are termed primary pollutants because they are health

risks in their unaltered state. They are largely from transportation sources (46 percent); fuel combustion in a stationary source such as power plants, incinerators, and refineries (29 percent); industrial processes such as manufacturing, smelting, and mills (16 percent); miscellaneous sources such as volcanoes, forest fires, ocean waves (salt spray), continental dust, pollen and spores, and the like (7 percent); and solid waste disposal (2 percent). Of these primary pollutants, the most abundant in the atmosphere is carbon monoxide (CO), which constitutes about 48 percent of the total air pollutant weight followed by sulfur oxides (16 percent), nitrogen oxides (16 percent), volatile organic compounds (VOCs) (15 percent), and particulate material (5 percent). These numbers vary by location and by season. Essentially every place on Earth contains some sort of primary air pollutant; the hazardous areas are those where the concentrations are high. Human response to primary air pollutants ranges from respiratory discomfort and watery eyes to death, either quickly or after long-term exposure. The London “Killer Fog” in the United Kingdom in 1952 killed thousands of people outright, in contrast to exposure to atmospheric asbestos or benzene, which are carcinogenic and can induce lung cancer over time. Nearly 200 million tons (181.8 million metric tons) of criteria air pollutants were emitted in the United States in 1997.

# R

**radiation** There are numerous forms of radiation that people are exposed to on a daily basis. Some are dangerous, whereas others are not, and still others may or may not be. There are three major sources of radiation: cosmic, or extraterrestrial; from earth materials; and from assembled equipment and devices. Cosmic, or extraterrestrial, radiation includes solar radiation and cosmic rays. It is a mixture of many different types of radiation with varying intensity and health implications. Radiation from earth materials is the result of the decay of radioactive isotopes of elements in minerals and other materials that is present everywhere on Earth. Equipment can produce a number of different types of radiation, both dangerous and benign. Sources can be directed toward a target such as X-ray machines or can sim-

ply be electric and magnetic fields (EMFs) that emanate from electrical equipment or power lines.

The amount of radiation that a person is exposed to is called the radiation dose or dosage. There are three types of doses: Absorbed dose is the amount of radiation energy that is deposited per unit mass of the target; it is usually measured in roentgen absorbed dose, or rads. Recently, rads are being replaced by grays, which equal 100 rads. Equivalent dose is the absorbed dose that has been adjusted for the biological effect produced by the particular type of radiation that is being measured; it is measured in roentgen equivalent man, or rems. The committed dose, the third type, accounts for continued exposure over decades or even a lifetime. Most daily doses of personal radiation are measured in millirems (mrems).

Checking for drum leakage at the low-level radioactive waste disposal facility, Idaho National Laboratory, ca. 1977 (DOE)

## TYPES OF RADIATION

There are several types of radiation to which people can be exposed. The most common is electromagnetic radiation that is emitted by the Sun and stars as well as many manufactured devices. The electromagnetic (EM) spectrum is classified by the wavelength and frequency of the waves in the radiation. The long-wavelength, low-frequency, and low-energy radiation is considered to be nonionizing radiation. The end of this side of the EM spectrum is characterized by amplitude modulated (AM) radio, shortwave radio, frequency modulated (FM) radio, and television, in order of increasing frequency and shorter wavelength. The next are microwaves, radar, infrared light (IR), and finally visible light. The EM radiation with shorter wavelength, higher frequency,

**Pinellas Plant, St. Petersburg, Florida, ca. 1979** (*Time Life Pictures/Department of Energy/Getty Images*)

and higher energy than visible light is ionizing radiation. In increasing order, they are ultraviolet radiation (UV), X-rays, and gamma radiation. Ionizing radiation is damaging to human health.

The age-old enigma of photon release in EM radiation means that it can also be included in the particle emission radiation. When radioactive elements decay, they convert from a parent isotope to a daughter isotope. This decay includes the emission of particles that have atomic number, mass, and charge. By removing such particles, the atom converts from one element to another through a decay series. The largest particle that can be emitted is an alpha particle. It is equivalent to a helium atom in mass and charge. Although the decay is fairly energetic, because of their mass, they only travel about one-half inch (1 cm) before they use up energy. Their size makes them unable to penetrate paper, skin, glass, and most substances. They can only be damaging in cuts or internal organs. A beta particle, or betatron, is essentially an electron that is emitted during beta decay in which a neutron is converted into a proton. Their smaller size allows them to penetrate paper and some solids, although they cannot penetrate skin. They are only hazard-

ous to the health if they are ingested. Gamma and X radiation can penetrate most substances. That is why X-rays are used to probe the interior organs and bones.

Electric and magnetic fields (EMFs) are lines of force that surround any operating electrical device, as well as transmission lines and electrical distribution equipment. EMF can be subdivided into three types. Extremely low-frequency (ELF) fields generally have frequencies up to 300 Hz. Intermediate-frequency (IF) fields have frequencies between 300 Hz and 10 Mhz, whereas radiofrequency (RF) is between 10 Mhz and 300 Ghz. ELF is emitted from power supplies and electric appliances, IF is emitted from computer screens and security systems, and RF is produced by cell phones, television, radio, and microwave ovens.

### SOURCES OF RADIATION

There are several major sources of radiation: extraterrestrial, material, and equipment or anthropogenic. Extraterrestrial includes both the EM spectrum (solar) already described and cosmic radiation. Cosmic radiation is that radiation generated

from outer space and by the Sun: It provides a constant bombardment of the Earth and contributes about 8–13 percent of the background radiation of Earth. There is direct radiation from space generally in the form of microwaves, but it is also from interaction of the atmosphere with cosmic rays.

Cosmic rays are highly charged particles that strike the Earth's atmosphere. About 90 percent of the particles is protons, 9 percent is helium atoms, and 1 percent is electrons. Cosmic rays originate from neutron stars, supernovas, and black holes outside the solar system but both within and outside our galaxy, though the Sun also emits anomalous low-energy cosmic rays from solar flares. There are primary cosmic rays, which are emitted directly from the source, and secondary, from collisions with other particles in space. When cosmic rays enter the Earth's atmosphere, they collide with oxygen and nitrogen molecules and produce a cosmic ray shower of mesons, unstable isotopes, gamma radiation, and neutrons. It is these interactions that change nitrogen 14 into carbon 14, which is commonly used for dating.

Cosmic rays are directed around the Earth by the magnetic field and are responsible for the aurora borealis. They are generally stronger at higher elevations but are dominated by protons very high in the atmosphere and more damaging neutrons lower in the atmosphere. Flying in an airplane increases the dosage from the cosmic radiation that results from interactions. For a typical cross-country flight, the dose is 2–5 mrems, which is generally small. People who fly often or fly near Polar regions, however, can be exposed to significant amounts of radiation, which could affect their health.

Earth materials also emit radiation. There are radioactive isotopes in most rock and soil but almost always in very small amounts. The common radioactive elements include uranium, radium, thorium, potassium, strontium, and radon, among others. Typically, elements within a decay series all occur together. A decay series is a step-by-step transition from a radioactive parent element through a series of daughter elements until a stable, nonradioactive daughter is reached. Decay series may have several tens of steps. Parent uranium decays to radium and

**Diagram showing the electromagnetic radiation spectrum of wavelengths in meters with illustrations of the relative wavelength sizes. The radiation is divided into ionizing and nonionizing and subdivided into types by common name. Illustrations of sources are also shown.**

then to radon on its way to stable lead. Depending upon the particular isotope, it may emit alpha or beta particles, but almost all emit gamma radiation. In some cases, these elements may be concentrated in a deposit. In these areas, there is risk of exposure to excessive amounts of gamma radiation, or, in the case of radon, alpha particles. In one case in Africa, so much uranium was concentrated in one place through natural processes that it began a nuclear reaction.

These types of occurrences of radioactive isotopes are called naturally occurring radioactive minerals, or NORM. If earth materials are processed and the radioactive minerals are removed as waste, they can produce dangerous concentrations called technologically enhanced naturally occurring radioactive minerals, or TENORM. The most common TENORM radioactive elements are uranium, thorium, and radium, which are derived from mining and mineral processing, oil and gas production, and drinking water and wastewater treatment.

There are also radioactive materials that are created by human activity whether on purpose or by mistake. The best known of the anthropogenic radioactive materials are used for defense, such as plutonium, or as a result of these activities, such as tritium. The other major uses of these materials are in medical procedures, sterilization, and some industrial applications. Many such isotopes are produced in a research grade nuclear reactor. Many are used instead of natural materials because the dosage and duration can be controlled better. The most common of these materials are cobalt 60, cesium 137, and technetium 99. Exposure can occur through medical procedures (mostly cancer treatment or diagnostic tests), to health care professionals applying these procedures or sterilizing instruments, in radiography during metal production, in sterilization of some foods and water, or through contact with the waste from any of the other uses.

The final sources of radiation are equipment and machinery. The simplest example of this is medical X-rays. This equipment generates X-rays directly to pass through parts of the body and onto special X-ray film to image the organ, tooth, or bone of interest. When X-ray equipment first became available, the equipment was leaky, was too powerful, and was used in too many applications, in shoe stores, for example. Nuclear power plants produce a lot of gamma radiation that can similarly pass through substances. That is why shielding by using lead or some other material that inhibits passage is very important. Other equipment bombards materials with high-energy particles, which, in turn,

generate secondary X-rays. This occurs mainly in high-energy analysis or related processes to which the public has very little access.

An enormous amount of equipment that is used every day produces EMF. Virtually all appliances, audio and video equipment, and computers produce it. The big scare in the past was the use of cellular phones. These are pressed against the skin for extended periods and produce EMF. Many studies have been conducted to determine whether there is a link between usage and disease, but none has yet been found.

### HEALTH EFFECTS OF RADIATION EXPOSURE

Ionizing radiation causes the most damage of any type of radiation exposure. Health effects from short-term high-dose exposure take the form of burns or radiation sickness. The more severe effect, radiation sickness, or radiation poisoning, produces a number of symptoms depending upon dosage. For an exposure of 5–10 rems, there can be rapid changes in blood chemistry. At 50 rems, nausea sets in within hours. At 55 rems, fatigue is added to the list of symptoms, and at 70 rems, vomiting begins. For an exposure of 75 rems, hair loss takes place within two to three weeks. At 90 rems, diarrhea begins, and at 100 rems, hemorrhage takes place. An exposure of 400 rems can be fatal within two months. At 1,000 rems, there are destruction of the intestinal lining and internal bleeding that ultimately leads to death within one to two very painful weeks. At 2,000 rems, damage to the central nervous system and loss of consciousness occur within minutes, and death follows in hours to days.

Long-term chronic exposure to low levels of ionizing radiation can also produce health effects. The main effect is cancer of many parts of the body. It can damage deoxyribonucleic acid (DNA) and produce genetic problems that can be passed on to offspring. If a pregnant mother is exposed to radiation, the fetus can be damaged as well.

Ingestion and inhalation of radionuclides can also cause severe health effects, typically over a lifetime of exposure. Radon is the most dangerous radiation source and the most dangerous environmental hazard. Unlike ionizing radiation, radon mainly damages human health with particle decay and specifically alpha decay. Normally, alpha decay is not a worry because the particle can only travel about  $\frac{1}{2}$  inch (1 cm) and cannot penetrate anything. The problem with radon is that it is a gas and is inhaled in indoor air. It decays to polonium, a solid that sticks to the lung tissue or to dust that

then attaches to lung tissue. The alpha decay that polonium undergoes can cause the cells in the lung tissue to mutate, potentially leading to lung cancer. It is estimated that some 25,000 lung cancer deaths per year in the United States are the result of radon exposure.

Ingestion of radioactive iodine leads to high levels in the thyroid gland. The thyroid takes in iodine and does not discriminate between stable and radioactive. For this reason, it leads to increased incidence of thyroid cancer. Strontium 90 and radium 226 behave similarly to calcium in the bloodstream. They accumulate in the bones and teeth and contribute to increased incidence of bone cancer. Radon can also be ingested within water. It can travel throughout the body in the bloodstream. Theoretically, it could increase the incidence of all types of cancer, but so far it has only been linked to an increase in leukemia.

Solar radiation in general and all of the forms of ultraviolet radiation cause the severe negative health effects over a long term of exposure. They can also cause skin burns and even eye damage in acute exposure, as anyone who has fallen asleep at the beach will attest. These burns can be severe and result in skin damage to the point where other symptoms such as fever, headache, fatigue, and nausea appear. This condition is locally referred to as sun poisoning. Long-term exposure can increase the likelihood of skin cancer. Solar radiation, in general, is considered a known human carcinogen. Increases in skin cancer, primarily melanoma, as well as melanoma of the eyes and non-Hodgkin's lymphoma, were found to increase with exposure. Broad-spectrum UVR is also considered a known human carcinogen and also increases the incidence of eye and skin tumors. It has also been shown to cause DNA damage. Each of the components of UVR, Ultraviolet-A (UVA), UVB, and UVC, is considered reasonably anticipated to be a human carcinogen, all increasing the incidence of skin cancer. The damage to DNA by UVR is caused by UVB and UVC; UVC is the more damaging. Fortunately, that is the wavelength that is best absorbed by ozone, and very little reaches the surface in the midlatitudes. Therefore, UVB does about 90 percent of the genetic damage.

EMF is emitted by numerous electrical devices and especially electrical distribution facilities. The only sure health effect of EMF is general heating similar to a microwave oven. Studies on the effects of living under power lines have yielded conflicting results. Some have claimed an increased incidence of childhood leukemia from a purely epidemiologi-

cal approach. It is for this reason that the National Institute of Environmental Health Sciences of the National Institutes of Health concluded that exposure to ELF fields like those produced by power lines is a possible cause of cancer. The International Association for Research on Cancer of the World Health Organization agreed and issued the same ranking. The problem is that studies on laboratory animals found no such link, and many scientists believe that there must be another causative link.

### DAILY RADIATION DOSE

An average individual receives a daily dose of radiation from several common sources. The average equivalent dose for a person in the United States is 360 mrems. Some professions may increase exposure, as may some personal habits. The common sources of radiation include cosmic radiation that depends upon elevation. The higher a person lives, the more cosmic radiation he or she receives. Similarly, people who regularly travel by air are exposed to higher levels of radiation. Both of these sources can be significant, up to 100 mrems or more apiece. There is a terrestrial source of radiation from earth materials that depends upon where a person lives. In the Gulf Coast and Atlantic Coastal Plain, the average dose from the earth is 23 mrems. Within the body, radiation can occur in food and water, air, a plutonium-powered pacemaker, and porcelain crowns or false teeth. The major sources are radon in air at 200 mrems, depending greatly on where a person lives, and the pacemaker at 100 mrems. Radon is commonly the greatest source of environmental radiation. There are a variety of very low-level sources of radiation such as X-ray inspection of luggage, gas lantern mantles in camping, weapons test fallout, stone and cement building construction, television viewing, computer use, proximity to a coal or nuclear power plant, use of a home smoke detector, and nuclear medical procedures. Besides the last one, most are 1 mrem or less. Medical X-rays are a much higher dose, at 40 mrem apiece.

**radioactive waste** Radioactive waste contains either radioactive substances or materials that have been exposed to radioactive substances or radioactivity for long enough periods to make them a health concern. Although radioactive substances have been used for a long time, their disposal has only become an issue in about the past 50 years. Radioactive waste is divided into two types: low-level and high-level.

### LOW-LEVEL RADIOACTIVE WASTE

About 99 percent of all radioactive waste is classified as low-level. It is expected to remain of concern for about 300–500 years. The sources of most low-level radioactive waste are hospitals. It primarily results from medical treatments, radiation equipment, materials that have been exposed to radiation, and the handling of radioactive substances. The objects that make up low-level waste may include syringes, bottles and vials, cloth, or tools. Other major sources of low-level radioactive waste are research laboratories and manufacturing facilities. Industry, universities, and the military all conduct research using radioactive substances. The objects classified as waste include laboratory clothing, tools, syringes, and containers but may also include substances that have been irradiated in a nuclear reactor.

Although the Low-Level Radioactive Waste Policy Act of 1980 requires states to develop regional low-level waste repositories, few have complied. Over the past few decades, the number of repositories has actually decreased as the cost of disposal has soared. The residents of many states refuse to have nuclear waste stored near them.

Low-level waste is stored in drums either above- or belowground. The rusting and decay of the drums pose a threat to local groundwater supplies. Currently, the best place to store such waste is in shallow excavations above the water table, preferably in arid areas. The repositories should be as far from populated areas as possible.

### HIGH-LEVEL RADIOACTIVE WASTE

High-level radioactive waste is produced by nuclear power plants and the military. It is extremely dangerous, and great pains must be taken to protect both humans and nature from it. The most common of high-level radioactive wastes are spent fuel rods from a civilian nuclear power plant. These rods and other parts from decommissioned plants make up 94 percent of the radioactivity of all high-level waste. These components and most other forms of high-level waste are dangerous for thousands to millions of years. For example, plutonium must be kept away from the natural environment for at least 244,000 years, and there are longer-lived radioactive substances.

The major problem with high-level radioactive waste is what to do with it. There are about 430 nuclear power plants operating in 35 countries and potentially more in the future if several countries that are developing nuclear programs are truly not interested in weapons of mass destruction, as they claim, and their nuclear programs are for peaceful purposes.

*See also* COBALT; RADIATION; RADIUM; WAR AND POLLUTION; YUCCA MOUNTAIN WASTE REPOSITORY.

**radium** There have been numerous health scares nationwide about high levels of radium in drinking water. In many cases, the sources of these elevated levels are natural materials, and, as such, they generally cannot be removed and no person or company can be held liable. Areas with such natural problems include much of the western United States and especially parts of California, Nevada, Idaho, and Montana; midwestern states such as Minnesota and Wisconsin; and most of the crystalline Appalachians, including nearly the entire states of Maine and New Hampshire. Some anthropogenic sources such as radium dumps around old watch factories in New Jersey and Michigan have also produced dangerous conditions. It is the debate over whether a problem is natural or anthropogenic that keeps radium in the limelight of environmental problems. Its notoriety would not otherwise have been expected because radium has been found in only 18 of the first 1,177 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priority List) in which it was analyzed. Yet, on the 2007 CERCLA Priority List of Hazardous Substances, of the 275 hazardous substances, radium 226 ranks number 95, radium 228 ranks number 106, and general radium ranks number 100. It is the wide distribution, health threats, and uncertainty of its source that make radium such a danger.

### PROPERTIES, USE, AND PRODUCTION

Radium is a naturally occurring radioactive metal that occurs in the form of a silver-white solid in pure form but is more commonly in compounds. It is present in virtually all rock, soil, and sediments as well as air and groundwater in many areas. It occurs in numerous isotopes that are daughter products in the radioactive decay series of uranium and thorium. The two most common isotopes are radium 226 and radium 228, daughters of uranium 238 and thorium 232, respectively. It, therefore, is more common around uranium deposits and especially uranium mining operations. Radium is luminescent (glows in the dark) and a good source of gamma radiation. It is most abundant in the mineral pitchblende, but it also occurs in salts such as radium nitrate, chloride, iodide, sulfate, and carbonate.

Radium was discovered by the French Nobel Prize winner Marie Curie, in 1898, in the mineral pitchblende, but it was not isolated in elemental form until 1911. When it first came into use in the early 1900s, it was added to a variety of common products such as tonic, toothpaste, ointments, and elixirs, until it was banned because of the adverse health effects. Its luminescence and phosphorescence when mixed with phosphorus gave it broad use in instrument panels, watch and clock faces, and anything else that glowed in the dark. This application continued through World War II and, in some cases, until the early 1960s. More recently, it was used as a radiation source in cancer treatment. Radioactive seeds that were planted in tumors were first composed of radium, but more recent applications largely use cobalt 60 as a source. Recent and current uses of radium include industrial radiography to detect flaws in metal parts and, mixed with beryllium, in oil well logging to detect different layers. It also has many minor uses in analytical research equipment and even on the tips of lightning rods to ionize the air, thus attracting strikes.

### ENVIRONMENTAL RELEASE AND FATE

Radium is ever-present in nature in very small quantities. It is even locally present in large quantities as the result of completely natural processes. Radium can never be rendered harmless by reactions or microbial activity. It can only be changed by natural radioactive decay with a removal half-life of 1,620 years for radium 226, 5.77 years for radium 228, and 3.64 days for radium 224. Radium is associated with uranium deposits, phosphate deposits, and certain rock types and geologic provinces. Anthropogenic radium in the atmosphere is primarily from coal-fired power plants and less commonly from

other burning of fossil fuel, windblown dust from uranium mining, and incineration of waste containing radium. The radium is diluted in the atmosphere and either settles out by gravity or is washed out by precipitation. The average residence time for fine particles in the atmosphere is about one to 10 days. The concentration of radium in glacial ice, however, has increased by a factor of 100 over the past 80 years, indicating that it may reside in air for long periods and be widely dispersed. The sources of this atmospheric radium are thought to be fossil fuels.

Anthropogenic radium in water and soil is primarily from runoff from uranium mining operations, air pollution fallout around atmospheric sources, lime slurry from water softening, fly ash disposal from incinerators, and coal burning. There is approximately 97 million tons (88.2 million metric tons) of uranium tailings in the western United States. Canada generates about 10 million tons (9 million metric tons) of uranium tailings per year. Radium in salts is generally increasingly soluble in water with increasing pH depending upon the minerals in which it is contained. Leachate from uranium tailings has been found to contain significant radium content. It is removed from surface water either by settling into the sediment or precipitating as sulfate, commonly with barium sulfate. Radium readily binds to soil particles and generally remains immobile under most conditions. Under certain relatively common chemical conditions, however, it may be leached into groundwater.

The other way radium can be removed from soil is through uptake by plants, which occurs quite readily. Grasses can take up radium, and cattle graze on the grasses. By this process, radium can enter in beef and milk. Aquatic organisms can similarly take up radium from water and sediment. Bioconcentration factors for fish are only one to 60 for fleshy parts but 40–1,800 for bones. Radium can also biomagnify up the food chain, posing particular danger for humans.

### HEALTH EFFECTS FROM EXPOSURE

There are no acute effects of exposure to radium unless the dosage is far beyond any dosage that a human would have even a chance of experiencing. Long-term, chronic exposure can lead to a number of health problems, but they typically take years to decades to develop. In general, the gamma radiation from radium will damage the closest body part. Workers who painted luminous dials licked their brushes to sharpen them only to have their teeth become weak and brittle. The term *radium jaw* was coined in 1924 to describe the loss of teeth among

these workers. Cataracts and cancer of the sinuses were much more common among this group than among the general population, as well. From 1925 to 1965, a number of women were treated with radium for uterine bleeding disorders. This group had a greater incidence of uterine, colon, and genital cancer, as well as leukemia. General application of radium also has adverse effects. From 1946 to 1950 in Germany, young tuberculosis patients were injected with radium and were subsequently significantly shorter than the general population. It also causes anemia and greatly increases incidence of bone cancer and generally increases incidence of liver, breast, lymphatic, thyroid, and pancreatic cancer, as well as leukemia, among other cancers. The EPA, National Academy of Sciences, and several other agencies all consider radium a known human carcinogen. The greatest public health danger of radium, however, is that it decays to form radon, a far greater threat.

### REGULATIONS ON HUMAN EXPOSURE

Federal agencies limit the exposure of the general public to radium. The EPA set a maximal level of radium in drinking water at 5 picocuries per liter for any combination of radium 226 and radium 228. They further set a limit of radium 226 in soil from mine tailings at 5 picocuries per gram for the top 15 cm and 15 picocuries per gram at deeper levels. The National Emission Standards for Hazardous Air Pollutants limit radium emission to air to 10 millirems. The Uranium Mill Tailings Control Act restricts the disposal of waste uranium at mines and processing plants.

**radon** Radon is a naturally occurring odorless, colorless radioactive gas that is estimated to be responsible for as many as 25,000 deaths per year of lung cancer in the United States alone. These statistics from the U.S. Environmental Protection Agency (EPA) make radon the most dangerous environmental hazard. On the 2007 CERCLA Priority List of Hazardous Substances, of the 275 most dangerous pollutants, radon ranks number 105. Radon is just one step in the decay series from uranium 238 to lead (Pb) 206, both of which are naturally occurring. There are about 22 steps in this decay series, in which a series of alpha and beta decays transform the parent uranium atom into radioactive daughter isotopes of a number of elements. One step in this series is radium 224. If the radium is on the surface of a mineral, when the next alpha decay occurs, a process called alpha recoil may eject the radioactive atom off the grain and into the pore space within sediments or soil. Radon 222 is the only gas in the decay series; all others are solid. It is also a noble gas and, therefore, will not react with any other substance; nor can it be filtered from the air by using conventional methods. Most radon is either released into the air or decays to the next step in the series while still contained within the same rock or soil pore space where it was released.

### ENTRANCE INTO INDOOR AIR

The problem occurs in a house that has a basement over soil or sediment containing radon. Virtually all soil contains some radon. Basements typically are not very tightly sealed, as they contain French drains, sump pumps, drains and/or holes, and cracks in the walls that permit soil gas to infiltrate the house. In the summer, there may not be much problem with infiltration because open windows eliminate pressure gradients and cooled air from air-conditioning is dense and sinks, pushing air through the openings and out of the house. In winter, however, when the air in the house is heated, it rises. Rising indoor air pulls air from the basement and draws soil gas through the openings in the basement walls and floor. This air commonly contains radon. Forced air heating and cooling systems may

do this all year long. Radon is then in the house and free to circulate.

### HEALTH EFFECTS OF RADON EXPOSURE

Radon itself is not particularly dangerous, but because it is radioactive, it changes to another element. The half-life of uranium radioactively decaying to its daughter product lead is a slow 4.6 billion years, but radon decays to its daughter polonium 220 much faster. The decay half-life (the time for one-half of the

mass of radon to change to polonium) is only 3.82 days. Polonium is a solid that reacts quickly. If the radon is in a person's lungs when the change takes place, the polonium adheres directly to lung tissue. If the radon is in air, the polonium may stick to a dust particle and be inhaled into the lungs. Polonium undergoes an alpha decay, emissions of a short-lived, heavy particle, producing 7.6 million eV in a matter of seconds. Normally, alpha decays or particles are not dangerous at all. At 4 atomic mass units per atom, they are so large that they cannot penetrate glass

Diagram showing potential entries for radon into a building, where it may accumulate to dangerous levels

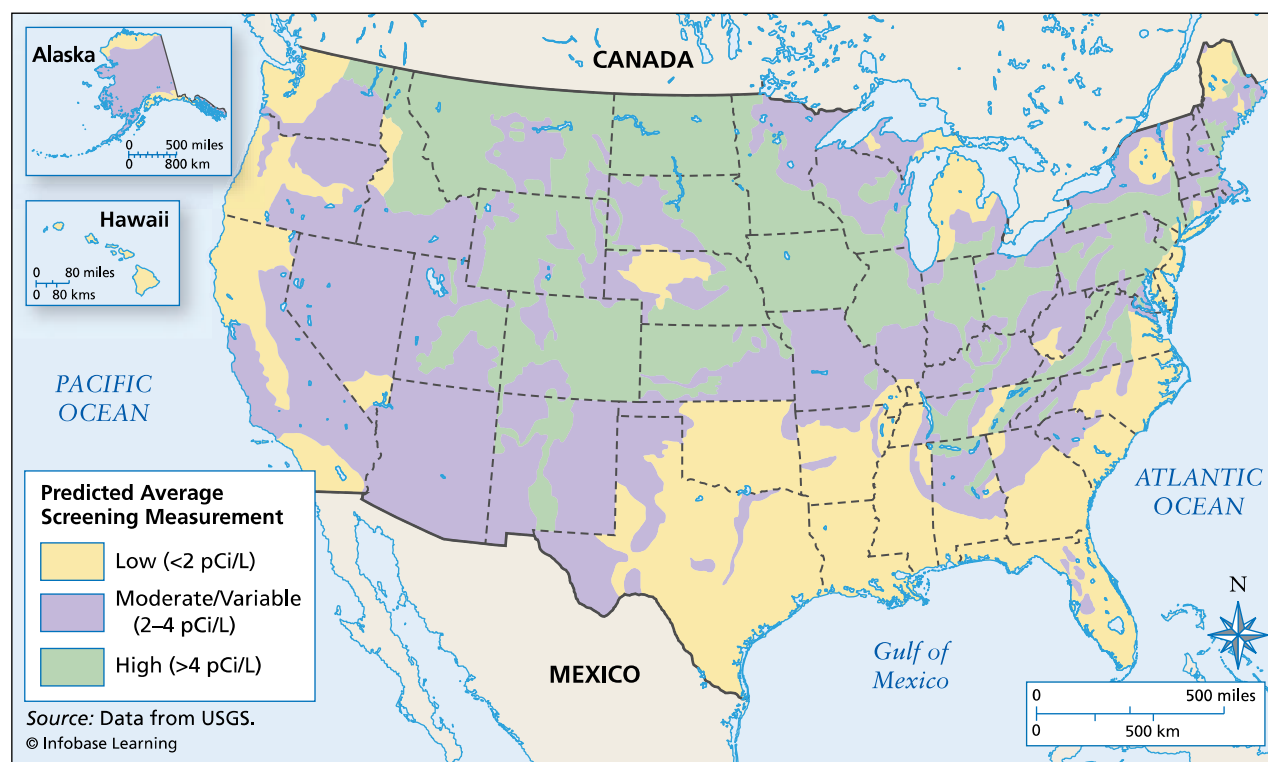

or paper, and they are so heavy that they can only travel about a half-inch (1 cm) before exhausting their energy. When sticking directly to lung tissue, however, the alpha particle can cause the attached lung cell to mutate. Each additional decay in the series all the way to lead 206 can cause additional damage to the same cell. Lung tissue has resiliency and can dispose of the random mutated cell without much problem. If there are a number of mutated cells, however, the immune system may be overwhelmed, and the person affected may develop lung cancer.

Radon was historically not considered to be a problem. The first indication that it might be was an epidemiological study in the 1970s of Swedish uranium miners who showed a significant increase in lung cancer relative to the general population. It was never suspected that radon could pose a threat to homes. A contributing factor to radon's becoming a health hazard was the energy crisis of the 1970s. In an effort to save energy, houses were sealed as tightly as possible to reduce the infiltration of outside air and loss of conditioned indoor air. Whereas previously radon concentrations were diluted by outside air, which contains little to no radon, in a tightly sealed house, radon could now concentrate in indoor air.

The first indication that indoor radon could pose a health threat was in 1982. The concentration of radon in the Swedish uranium mines was approximately 700 picocuries per liter (pCi/L), which was considered to be extreme compared to indoor levels. A home in Boyertown, Pennsylvania, however, was found to contain 3,200 pCi/L. This concentration is even more alarming when compared to the action level established by the EPA years later of 4 pCi/L. An action level means that remedial methods must be enacted to reduce the levels. Radon mania ensued through the 1980s and most of the 1990s. Homes could not be sold without acceptable radon test results. Charlatans ran amok with everything from jars to fly paper offering to test for and reduce radon. After a few years, however, methods were standardized and the industry settled into reputable companies. The highest indoor radon concentration ever recorded was in Clinton Township, New Jersey, at 3,500 pCi/L.

### MEASURING RADON IN HOMES

Radon in indoor air can be measured in several ways, the most common of which are the charcoal canister and the alpha track. The charcoal

**Generalized radon potential map of the United States based upon geology. It is a potential map because radon accumulation depends more on housing construction than on geology. If a house is built on a slab with no basement and with public water, there is no way to have a radon problem regardless of the geology. Therefore, the comparison can only be made for a specific type of house in each of these areas. (Source: USGS)**

canister is much most commonly used and is the only method used by building inspectors. With the basement sealed, the lid on a canister of activated charcoal is removed, and it is exposed to the indoor air for up to three days. The canister is resealed and sent to a laboratory for analysis, where the amount of radon daughters is determined. This method gives a snapshot of the indoor radon conditions and, therefore, is subject to weather, water usage, and other factors that can radically vary the concentrations. The alpha track method involves exposing a strip of alpha-sensitive film to indoor air for a period of three months. Alpha decays from the radon and its daughters leave small marks on the film, which are then counted to yield concentrations. This long-term test yields the average radon concentration in a building, which is more useful than the charcoal canister method as an indicator of exposure and threat to health. Radon is considered dangerous only for long-term exposure, on the order of tens of years.

Radon can also enter groundwater if the soil or sediment is saturated. It is released from the water if it is agitated and enters air. Water radon poses another problem for people who rely on wells for their household water needs. Radon can be released by simply running the water from the tap, but dishwashers, showers, and washing machines can also release much radon. Water can hold much higher concentrations of radon than air. The record is 2.5 million pCi/L, but levels in the tens to hundreds of thousands are not uncommon. The EPA recently set the action level at 10,000 pCi/L for water. A study at the University of Maine found that ingested water might also pose a threat. Subjects drinking water with moderate levels of radon were found to be exhaling air with significant radon levels after a 20-minute metabolic period. The radon was passing through their stomach and into their blood, circulating throughout their body, and leaving of their lungs with the regular metabolic carbon dioxide. All organs and blood are apparently exposed to radon through this process. The EPA and National Institutes of Health deem the dosage from this source to be too small for concern, but no rigorous epidemiological studies have been performed to prove this.

Radon may also result from industrial effects. Any industry that uses radium in its production has the potential to produce radon pollution. The most common culprits are old watch manufacturers. The luminous dial on analog watches is typically made of radium. Any industrial waste from these companies typically contains radium and, if improperly

disposed of, can cause an environmental hazard. The most famous case of this occurred in a Montclair, New Jersey, watch factory that tainted soil all around the town and into Glen Ridge and has taken decades for cleanup.

#### Reactive Metals Extrusion Plant Ashtabula, Ohio (1990–present) Soil Pollution

The dedication, creativity, and commitment of the people who worked in places such as the Reactive Metals Extrusion Plant (RMEP) in Ashtabula, Ohio, were part of the reason that the United States survived the cold war. About 60 miles (96.6 km) northeast of Cleveland on the shore of Lake Erie, the 26-acre (10.5-ha) RMEP site was part of the industrial complex that manufactured nuclear weapon components. In 1962, the Atomic Energy Commission (Nuclear Regulatory Agency, or NRC, after 1974)

licensed the placement of a 3,900-ton (3,538-metric-ton) extrusion press at Ashtabula. For the next 30 years, under contracts with the U.S. Department of Energy (DOE), RMEP manufactured metallic uranium tubes, rods, and forged uranium parts for use in atomic weapons. These products were cut, straightened, acid bathed, and machined before shipment to other weapons manufacturing facilities.

As did similar plants in Dayton and Fernald, Ohio, and Oak Ridge, Tennessee, RMEP operated under high security and with a single mission; to create reliable nuclear weapons as fast and inexpensively as possible. This was a time when America felt very threatened by the spread of communism and was competing in an all-consuming arms race with the Soviet Union and China. Even the great secrecy of nuclear weapons plants, however, could not hold off the public pressure that was building for environmental disclosure. By the early 1980s, with the end of weapons production and the need for plants such as RMEP starting to decline, it was time to assess the environmental damage caused by the operations.

### POLLUTION OF THE SITE

RMEP emitted mixed uranium metal and oxide dusts through six stacks and, over its operational life, released approximately 1,900 pounds (850 kg) of uranium. The soil around RMEP was contaminated with tiny fragments of uranium, as well as technetium 99, a fission product from recycled reactor material, and other metals used in its processing operations. These metals were released from process stacks and settled as fallout around the plant. They were also washed out of storage areas by rainfall and snowmelt. Core samples of the top two inches (5 cm) of site soil contained uranium concentrations ranging from 1.1 pCi/g to as high as 2,439 pCi/g. A typical background value for uranium in soil in this part of Ohio is 4.4 pCi/g or less. The NRC average limit of uranium in soil intended for unrestricted use is 35 pCi/g.

The amount of radiation exposure is usually expressed in a unit called a millirem (mrem). In the United States, the average person is exposed to an effective dose equivalent of approximately 360 mrem whole-body exposure per year from all sources. As radiation moves through the body, it either causes no damage to cells, damages cells in a way that they can repair, or damages cells in such a way that the damage is passed on when the cell reproduces. In the first two cases, there is no lasting health effect. In the third case, a delayed health

impact, such as cancer, may develop. If the dose is high and the exposure is long, the radiation may kill the cell. If this occurs, an immediate health effect is observed such as burns, nausea, or even death. Many radioactive substances tend to accumulate or concentrate in specific “target” organs such as the kidneys or thyroid. When this occurs, that organ receives a higher dose than other organs or tissues. This occurs because some radioactive materials are chemically similar to essential human nutrients. A commonly cited example is strontium 90, which is very similar chemically to calcium. Once it is ingested, the body will metabolize strontium in the bone in the same way it does calcium. Certain radionuclides are carried throughout the entire body. Tritium is an isotope of hydrogen, and, since hydrogen is part of the water molecule, tritium is carried to all parts of the body and delivers a dose to all tissues. Information on how radiation affects human health has been learned primarily from studies of survivors of the atomic bombing of Japan and industrial accidents such as at Chernobyl.

### THE CLEANUP

At RMEP, the widespread on-site contamination with estimated volumes of contaminated soil up to 64,000 tons (58,060 metric tons) made its removal and off-site disposal prohibitively expensive. Instead, the Department of Energy decided to use a remedial technique known as soil washing to recover the uranium and reclaim the land around the site.

Developed in Europe in the 1980s, soil washing is an ex situ remedial technique that uses water in combination with chemical additives to extract or wash out the contamination. The types of additives used include soaps, chelating agents to bond with metals, acids to dissolve them, and alkalis to precipitate them. Once the contaminant is separated, it can be properly disposed of and the clean soil returned to the site.

Soil washing works best if contaminants can be transferred to the wash fluid or concentrated into one part of the soil, most commonly the silt or clay fraction. After the contaminated soil is excavated, it passes through a series of sieves that separate the coarser grains from the finer silt and clay particles. The coarse sand and gravel are generally not contaminated and can be returned to the excavation without further treatment. A solution is then mixed with the silt and clay, and the resultant slurry is fed to a flotation or frothing/foaming device. Once it is there, the contamination can be skimmed off and

the clean silt and clay allowed to settle for drying, testing, and return to the excavation. If the contaminant cannot be separated easily from the silt and clay, then it is shipped for off-site disposal after drying. This process is more effective in soil with high percentages of sand and gravel. Soil with a high clay and silt content does not respond well, as the contaminant tends to bind with those smaller soil particles and becomes tough to separate.

At RMEP, the DOE and its cleanup contractors constructed a carbonate extraction plant that has remediated more than 14,000 tons (12,701 metric tons) of radioactively contaminated soil. In this process, the uranium-contaminated soil is mixed with a sodium carbonate solution. The uranium is taken out of the soil and dissolved into the liquid to form a carbonate complex. This carbonate solution is run through a series of columns where the uranium is captured by special resins and later flushed out by using sodium chloride. The system in use at RMEP can process up to 10 tons (9.1 metric tons) per hour, with 85–95 percent capture efficiency. DOE's contractor, the developer of this process, has estimated that the system has saved more than \$300 per ton (\$273 per metric ton) over other remedial options.

The chief challenge to using soil washing is the management of the water and chemical additives that are mixed with the soil. For a soil washing system to be cost-effective, the wash water and additives must be able to be recycled or reclaimed and be safe enough eventually to discharge to the environment without requiring extensive treatment or creating another hazardous condition.

At the end of the project, DOE will cease all operations in Ashtabula, leaving the extrusion plant in compliance with less than 30 pCi/g of uranium in soil. It is unlikely, however, that the site will ever be used for residential purposes, and its anticipated future purpose is likely to be some sort of industrial or manufacturing operation.

#### Revelle, Roger Randall Dougan (1909–1991) American Oceanographer, Environmental Advocate

When Roger Revelle received the National Medal of Science from President George H. W. Bush in 1990, he concluded that it was for being the "grandfather of the greenhouse effect." No one disagreed that he deserved the title, and it is for this achievement that he is best known, but his contributions to society are many. The *New York Times* called him "one of the world's most articulate spokesmen for science." It is difficult to forget the name *Roger Revelle* as it appears as the name of a college at University of California at San Diego, on a research vessel at the prestigious Scripps Oceanographic Institution, and in the public health building at Harvard University, but recently it became even more prominent. The 2006 Oscar-winning documentary *An Inconvenient Truth* by the former vice president Al Gore correctly identifies Roger Revelle as the discoverer of global warming and the greenhouse effect, as well as Gore's personal inspiration. It is on this global level that Roger Revelle is revered.

#### BIOGRAPHICAL INFORMATION

Born on March 7, 1909, in Seattle, Washington, Roger Randall Dougan Revelle was raised in Pasadena, California. He was recognized as a prodigy from a young age—he entered Pomona College, California, in 1925 at age 16, intending a career in journalism, till a class in geology fascinated him and he changed majors. In 1928, he met Ellen Virginia Clark, whom he married in 1931. Clark was a student at nearby Scripps College and the grandniece of the college's founder, Ellen Browning Scripps. Revelle graduated with a bachelor of science degree in 1929 and continued his graduate studies in geology

**Dr. Roger Revelle, head of Scripps Institute of Oceanography, March 1961** (Photo by Fritz Goro/Time Life Pictures/Getty Images)

at the University of California at Berkeley in 1930. His area of specialization was oceanography, and in 1931 he received a prestigious research assistantship, fortuitously at the Scripps Institute of Oceanography in La Jolla, California. During his time at Scripps, he also served as instructor. Revelle received his Ph.D. in 1936 and earned a postdoctoral fellowship at the Geophysical Institute in Bergen, Norway. In 1937, he returned to the United States to a position of research associate at Scripps Institution and part-time lecturer at the University of California at Los Angeles.

Roger Revelle was a reserve officer in the U.S. Navy and was called to duty in 1941. In 1942, he was assigned to the Bureau of Ships, where he conducted oceanographic research. By 1945, he was on the staff of the commander of amphibious forces for the Pacific fleet, where he helped plan the invasion of Japan. When the war ended, Revelle remained in the navy to participate in the first postwar atomic test

on Bikini Atoll, code-named Operation Crossroads. He led the Crossroads scientific program to study the effects on marine life, as well as remnant radiation in the rocks and sediment. In 1947, Revelle was transferred to the Office of Naval Research, where he was appointed head of the Geophysical Branch. There he established a model to support research at universities, which would later be used for the National Science Foundation. Revelle retired from the navy in 1948 as a commander.

Roger Revelle returned to Scripps Institution in 1948 and became its director in 1951. Under his leadership, Scripps became one of the leading oceanographic institutions in the world. He greatly expanded the fleet, participated in research cruises, and was personally involved in most of the great discoveries. Revelle established or was a key participant in nearly every major international committee on the oceans. He was also the major force in making Scripps part of the University of California at San Diego in 1959–60 where he served as dean. During this time, Revelle took a leave in 1962–63 to serve as science adviser to secretary of the interior, Stuart Udall, when he was instrumental in gaining recognition and acceptance for the work of Rachel Carson, whose book *Silent Spring* was released that year.

Roger Revelle switched directions in his career in 1964, when he accepted a position as Richard Saltonstall Professor of Population Policy at Harvard University, where he also served as director of the Center for Population Studies. He was especially concerned with food production in relation to population growth and again made his mark on the forefront of the field. In 1976, Revelle returned to the University of California at San Diego to be a professor of science and public policy, the extent of semi-retirement as he would allow himself. Roger Revelle died on July 15, 1991, in La Jolla, California, at age 82 of complications related to cardiac arrest.

### THE GREENHOUSE EFFECT

Before the mid-1950s, it was assumed by the scientific community that any excess carbon dioxide produced by human industry would be quickly absorbed by the oceans, keeping the atmospheric levels relatively constant. The new technique of measuring carbon isotopes allowed Hans Suess to distinguish normal carbon from that produced by human activities in 1955. Roger Revelle recruited Suess for Scripps Institution, and the two published a seminal paper in 1957, clearly demonstrating, with Suess's techniques, that the amount of carbon dioxide was

increasing in the atmosphere as the result of human activities. Revelle also attracted Charles Keeling to Scripps in 1956, and he began systematic measurements of carbon dioxide in the atmosphere at Mauna Loa, Hawaii, and in Antarctica. This basic research would be the foundation of the study of greenhouse gases and global warming. As a result, Revelle was asked in 1965 to serve on the president's Science Advisory Committee Panel on Environmental Pollution; through his influence, for the first time, carbon dioxide from the burning of fossil fuels was recognized as a potential global problem. Revelle served on many other international panels, spreading the concern for global warming, but he is probably best known for a popular article published in *Scientific American* in August 1982. This article not only showed and explained the increase in atmospheric carbon dioxide, it also described the effects on the Earth, including the melting of glaciers and ice caps, thermal expansion of the ocean, shifting of climate belts, and changes to the ocean and atmospheric circulation patterns.

### PUBLIC AND PROFESSIONAL RECOGNITION

Roger Revelle was one of the most decorated scientists of all time. In addition to the awards mentioned, Revelle was elected to the National Academy of Science in 1958 and was awarded their Agassiz Medal in 1963. He was awarded the order of the Sitara-Imtiaz in 1964 by President Mohammed Ayub Khan of Pakistan for his work on waterlogging and salinity. He was awarded the Balzan Prize for oceanography and climatology in 1986 by President Francesco Cossig of Italy. The American Geophysical Union awarded Revelle its highest honor, the Bowie Medal, in 1968, as well as the Tyler Medal in 1986. The University of California at San Diego even named a medal for excellence in education in his honor.

### Rocky Mountain Arsenal Denver, Colorado (1987–2012) Soil and Water Pollution

In the early days of World War II, the United States acquired, through the use of eminent domain, approximately 20,000 acres (8,000 ha) of flat, productive farmland 10 miles (16 km) northeast of Denver, Colorado. A massive round-the-clock building program then began, and, six months later, the nation's first chemical weapons and incendiary munitions manufacturing facility became operational. In the center of the country, far from more easily attacked coastlines, away from populated areas, and close to major rail lines, over the next four years the Rocky Mountain Arsenal produced more than 100,000 tons (90,718 metric tons) of gas, napalm, and other specialty munitions. It surpassed the combined German and Japanese production of these materials within the first year of production.

The Rocky Mountain Arsenal (RMA) was closed for a short time at the end of the war, but increasing tensions with the Soviet Union during the cold war and the need for incendiary munitions during the Korean and Vietnam conflicts resulted in the reactivation of the facility. Supplementing its purely military mission, RMA also helped manufacture the hydrazine and other rocket fuel that powered America's space program. Later, it leased a portion of the facility to Shell Oil Company for the manufacture of pesticides.

### POLLUTION OF THE SITE

During the 1960s and 1970s, chemical warfare agents continued to be produced at RMA, most notably GB nerve agent, better known as Sarin. RMA also played a major role in the decommis-

South Plants manufacturing complex at Rocky Mountain Arsenal, Colorado, ca. 1992 (© Wendy Shattil/Bob Rozinski)

sioning and destruction of obsolete and unwanted chemical and incendiary munitions. In order to manufacture and dispose of these munitions, RMA utilized enormous quantities of sulfur and chlorine with water. In addition, Shell Oil Company used water in its processing operations. This water was discharged into a series of unlined lagoons and holding basins. Liquids infiltrated and entered the regional groundwater system, and solids accumulated at the surface and sometimes washed into local streams and drainage swales. In other areas of the facility, chemicals from manufacturing and demilitarization processes were buried, incinerated, or simply poured into disposal trenches. At certain buildings, liquid wastes were discharged.

The community surrounding the RMA, a thriving suburb of Denver, began to notice the effects of these industrial activities. The availability of a reliable and plentiful supply of groundwater had been one of the key factors in the construction and operation of RMA, and this groundwater supply, which also served the surrounding communities, was being threatened.

## REMEDIAL ACTIONS

The army tried to remedy some of these problems through a number of short-term solutions. In 1956, a state-of-the-art waste holding evaporation pond with a capacity of 243 million gallons (918 million L) was installed with an asphalt liner and chemically sealed vitrified clay pipes that carried the liquid wastes. Despite this effort, by 1962, complaints about tainted groundwater in off-post drinking water wells were increasing. The army decided to drill a two-mile- (3.2-km-) deep waste injection well for the disposal of liquid chemicals. This well was intended to dispose of wastes far below the land surface in a geologic horizon that would not be used as a drinking water supply. Although it was not as efficient as planned, more than 170 million gallons (643 million L) of liquid waste was pumped into this well and permanently disposed of in the subsurface. Within a few years of its operation, however, a series of small earthquakes occurred in the generally aseismic Denver area. After a series of geologic studies, geophysicists concluded that the injection of liquid wastes deep into the subsurface by the RMA

disposal well was acting as a lubricant for a series of ancient faults and was causing the earthquakes. Deep-well injection at RMA ended shortly after that report was issued, and so did the earthquakes.

By the 1970s, it had become clear that RMA operations had severely affected local groundwater quality. The facility was added to the National Priorities List as a Superfund site in 1987, and its mission formally changed from military applications to environmental

restoration. Contaminants detected in groundwater include organochloride- and organophosphate-based pesticides; carbamate-type insecticides; chlorinated solvents, primarily tetrachloroethylene (PCE) and trichloroethylene (TCE); heavy metals; and feedstock chemicals used as raw products or intermediates in the manufacturing process.

Remedial efforts at RMA have cost billions of dollars and are expected to continue well past 2012. Four large pump-and-treat systems prevent the migration of contaminated groundwater from severely affected areas on- and off-post. More than 1.2 billion gallons (4.5 billion L) of captured groundwater is treated and either released to the area's municipal sewer system or recharged to help flush residual contaminants out of the ground. In other parts of the property, buried wastes have either been excavated, stabilized, and placed in secure disposal units on the property or been entombed in situ. This method involves surrounding the waste with low-permeability slurry walls and covering it with specially designed long-term earthen caps. Investigations continue on ways to address the products of more than 30 years of important and essential military manufacturing activities safely and cost-effectively. Shell Oil also has acknowledged its role in the spread of contamination and is working cooperatively with the army and state of Colorado to address soil and groundwater contamination related to its operations.

As cleanup operations began to improve environmental quality, government officials recognized they had a unique opportunity to restore most of this land to the public. In 1992, the Rocky Mountain Arsenal National Wildlife Refuge Act was passed and signed by President George H. W. Bush. This act allows the majority of the site to become a national wildlife refuge under the jurisdiction of the U.S. Fish and Wildlife Service. Portions of the property will be sold to local communities for road improvements and commercial development, but the vast majority of the 20,000-acre (8,000-ha) site will be restored and maintained for the enjoyment of the public. In 1997, approximately 6,000 acres (2,400 ha) of the site was removed from the National Priorities List, and in 2006 another 7,200 acres (2,880 ha) was transferred. This makes the Rocky Mountain Arsenal Wildlife Refuge one of the largest urban wildlife centers in the United States. It is habitat to bald eagles, bison, and more than 300 other species. Another 11,000 acres is scheduled for inclusion in the refuge by 2011.

**Illustration of a deep high-pressure injection well for hazardous waste like the type that was used in the Rocky Mountain Arsenal. The idea is to place the waste deep enough that it cannot affect humans or the environment. The three potential problems shown are: spills at the surface (1), leaks in the well casing (2), and leakage through rock strata (3). A new problem was found in the Rocky Mountain Arsenal when the wells started generating earthquakes.**

# S

**Safe Drinking Water Act (SDWA)** The Safe Drinking Water Act (SDWA) was enacted by the U.S. Congress in 1974 as public pressure to regulate pollutants in the environment mounted. This legislation was originally designed to protect public health by regulating the nation's public drinking water supply. This initial legislation was amended twice, once in 1986 and again in 1996, to protect drinking water further with stricter and more far-reaching controls. They also provided some protection to the environment by considering the water sources such as rivers, lakes, reservoirs, springs, and groundwater wells. The SDWA authorizes the U.S. Environmental Protection Agency (EPA) to set the national health-based standards for drinking water. These standards protect drinking water against both naturally occurring and anthropogenic contaminants. The EPA, state governments, and water supply systems work together to make sure the standards are met.

The naturally occurring contaminants that are addressed by SDWA include microorganisms that are naturally contained in water and soil, radionuclides, nitrates and nitrites from soil, fluoride, and heavy metals, including arsenic, cadmium, chromium, lead, and selenium that are derived from bedrock and soil. Contaminants from human activities have a number of sources. Human and animal wastes are derived from septic tanks, and farms may contain bacteria and nitrates. Heavy metal contaminants are derived from mining, construction sites that use equipment and metal components, and older orchards. Other contaminants from outdoor applications include fertilizers and pesticides from agricultural and landscaping activities. There are industrial products and wastes from local factories and production and dis-

posal activities from industrial plants that are also monitored. Gas stations, dry cleaners, leaking home underground storage tanks (USTs), municipal and local landfills, and dumps are dominant sources of contaminants from urban and suburban residential areas. Even private residences generate contaminants from household wastes including solvents, used motor oil, paint and paint thinner, lead and copper from household plumbing, and even water treatment chemicals from wastewater treatment plants.

There are now about 170,000 public water systems that provide water to virtually all Americans at some point in their lives. More than 273 million Americans receive water from 53,000 community water systems. The EPA, individual states, tribes, municipalities, water supply systems, and the general public bear the responsibility for making sure these public water systems provide safe drinking water. The SDWA provides the organization for these groups to work together to accomplish this.

## DEFINITION OF WATER SUPPLIES

To be considered as a public water system, there must be at least 15 service connections or at least 25 people served per day for 60 days of the year. Single-residence (family) wells are not regulated by SDWA. The drinking water standards are applied to water systems on the basis of their type and size. Water systems are divided into the following categories:

*Community water system.* A community water system is a public water supply system that serves the same people throughout the year. Most residences, including homes, apartments, and condo-

miniums in cities, small towns, and mobile home parks, are served by these systems. There are approximately 54,000 community water systems in the United States.

*Noncommunity water system.* A noncommunity water system is a public water supply system that serves the public but does not serve the same people throughout the year. There are two types of noncommunity systems: nontransient noncommunity water systems and transient noncommunity water systems.

*Nontransient noncommunity water system.* A nontransient, noncommunity water system is a public water supply system that serves the same people more than six months per year, but not throughout the year. An example of such a system might be a regular academic year school (no summer activity) with its own water supply. There are approximately 20,000 nontransient, noncommunity water systems in the United States.

*Transient noncommunity water system.* A transient noncommunity water system is a water supply system that serves the public but not the same individuals for more than six months at a time. An example of such a system might be a rest area or campground where the water may be used throughout the year but the same people are not using it. There are approximately 89,000 transient noncommunity water systems in the United States.

## ESTABLISHING DRINKING WATER STANDARDS

The EPA has set primary drinking water standards according to the following three-step process:

- 1) Identification of the contaminant. The EPA identifies contaminants that may adversely affect public health and are occurring in public drinking water supplies with a frequency and at levels that are of concern. The EPA identifies these contaminants for detailed study and, using those results, determines the contaminants that may require regulation.
- 2) Determining maximal contaminant level (MCL). The EPA determines a maximal contaminant level goal for contaminants that meet the criteria for regulation. The MCL goal is the level of a particular contaminant found in drinking water below which there is no known or expected risk to health. These goals are based upon numerous scientific studies and are designed to include a margin of health safety.
- 3) Legislating enforceable standards. The EPA determines the MCL, which is the maximal permissible level of a particular contaminant in drinking water that will be delivered to all subscribers of an individual public water supply system. These levels are enforceable standards under the law and are established as close to the MCL goals as is feasible under the prevailing conditions. The SDWA defines *feasible* as the level that can be achieved using the best technology, treatment techniques, and other means at a cost of attaining those goals that EPA considers available and reasonable. If it is not economically or technically feasible to set a maximal level, or if there are no reliable or economic methods to detect contaminants in the water at the required levels, the EPA instead sets a required treatment technique that specifies a required method of treating the water to remove contaminants.

The water quality standards established through the SDWA are now in effect throughout the United States. The passage of this important bill ensures that all Americans who have public water supplies have clean water. As increasing numbers of Americans switch from well water to public water supplies and as SDWA is applied to smaller public water supplies, more people will be under the protection of SDWA. In the long term, it will promote a healthier population and reduce outbreaks of disease.

**saltwater incursion** A very important problem for the majority of coastal communities around the world is saltwater incursion. The problem in these areas is that freshwater needed for survival meets unpotable salt water of the oceans. The salt water, by virtue of its saturation with heavy ions, is denser than freshwater and infiltrates the deeper aquifers. Freshwater is mainly introduced by precipitation and to a lesser extent by streams and rivers. Both because it is less dense and because it is introduced to the surface, freshwater fills surface pools and the shallow aquifer. The freshwater forms a wedge thinning to nothing as it approaches the shore and thickening inland. It sits atop the salt water that forms the entire deeper water supply. Unless water is piped in, shore residents must rely on the shallow water wedge for their drinking water supply.

The water supply in these areas is highly sensitive. Any substance released to the surface quickly percolates into the groundwater because of the high permeability of the sandy soils of coastal areas. Seemingly inconsequential activities such as lawn care and gardening (herbicides, pesticides, and fertilizer) can actually damage the water quality as much as most chemical spills because of the relatively huge volume of application. This sensitivity of the water supply may be the reason that these areas typically have a much higher cancer rate than inland communities.

### WELLS AND WATER USE

Residential and community wells in coastal areas must be shallow. They attempt to siphon the freshwater off the saltwater. If pumping wells draw too hard, they will cause a cone of depression in the water table. As with most cones of depression, if the well draws water faster than it can be replaced, it may go dry. Shallow wells are more prone to running dry than deep wells because there is less water available. Another problem is also encountered in coastal areas. Pumping wells may draw the salt water–freshwater interface upward toward the well bore as the freshwater is removed. If the draw is too strong, this interface may rise up to the well, which may start pumping salt water. Not only can the water not be used until the interface returns to a lower elevation than the bottom of the well, but many household items that could be damaged may be exposed to salt water.

In relatively densely populated coastal communities where there are numerous residential wells,

a more serious problem may arise. The freshwater wedge is generally limited in size and is commonly only replenished by precipitation. If the community draws too heavily on the wedge, it may shrink in size and volume. Instead of reaching nearly to the coast, the thin edge may withdraw far inland so that there is no freshwater at all beneath the houses closest to the beach. In some areas, this could make some houses uninhabitable. The number of houses potentially affected by saltwater incursion depends upon the density of housing and water demand of the community away from the shore.

Saltwater incursion creates particular problems in coastal communities of the highly populated East Coast. Long Island, New York; the New Jersey shore; and the Maryland shore have several areas where it has become a significant problem. Other areas, in California, Texas, and Florida, have also reported the same problem. It is for this reason that many coastal communities have switched to piping in freshwater from nearby rivers and only using their groundwater supply to supplement the drinking water supply during heavy use periods. This practice has reduced the stress on the freshwater wedge, but increased coastal building can easily overwhelm the fragile system.

**Block diagrams showing two potential problems with pumping groundwater wells in coastal regions:** Lighter freshwater from precipitation sits above denser salt water from the ocean at the shore, but a pumping well may draw up the saltwater interface into the well (A); and in addition to drawing salt water up into the well, a pumping well may form a cone of depression in the water table that makes the well go dry (B).

**Santa Barbara oil spill** *Santa Barbara Channel, California (January 28–February 8, 1969)* *Water Pollution* If there is a directory of seminal events that formed America's environmental consciousness, the 1969 Santa Barbara oil spill would certainly be near the top. The daily images of the Santa Barbara oil spill on the evening news mobilized the nation and led to some of the most far-reaching opinion and public policy changes since the Great Depression.

### BACKGROUND

Along the coastline of Santa Barbara County, California, there are two east-west-oriented geologic basins, formed over millions of years of plate tectonic movements and changes in sea level related to glaciation and climate change. Both the Santa Maria Basin, which is 150 miles (241.4 km) long by 10–50 miles (16.1–80.5 km) wide, and the Santa Barbara–Ventura Basin at 185 miles (297.7 km) long and approximately 55 miles (88.5 km) wide, host large reserves of medium- to heavy-grade crude oil, as well as significant quantities of natural gas. The Santa Maria Basin contains up to 500 million barrels (79,500 million L) of petroleum and billions of cubic feet of natural gas.

Union Oil of California drilled a 3,500-foot- (1.1-km-) deep oil production well from an offshore platform named Alpha, into the heart of the Santa Maria Basin. During drilling, steel casing is used to brace the open hole and to prevent surrounding sediments from filling it in. Eventually, the steel casing is seated, or driven deep into the bedrock, to form a tight seal between the top of the borehole and the bottom of the seafloor. Union Oil received a variance from the U.S. Geological Survey to seat the bottom of the steel casing at a depth much shallower than allowed by California state regulations. The Alpha platform was 5.5 miles (8.8 km) offshore, well outside California's three-mile (4.8-km) coastal zone, and did not have to comply with state standards, which were much stricter and more expensive than those of the federal government.

Oil, gas, and water present deep below ground in the rocks of the Santa Maria Basin are under tremendous pressure. To prevent the sudden, uncontrolled rush to the surface of these materials during drilling called a blowout, drilling mud is pumped into the borehole. This mud is kept at the same pressure as the oil, gas, or water in the geologic formation being tapped and forms an effective barrier to their release, thus helping to prevent blowouts.

### THE OIL SPILL

During the morning of January 28, 1969, workers removed a section of pipe from the borehole to replace

a broken drill bit on platform Alpha. They had not pumped enough mud into the borehole to compensate for the loss of volume caused by the removal of the drill pipe. This allowed a sudden increase of pressure to occur inside the borehole. This increase in pressure split the upper part of the steel casing, which, because of the variance, had not been installed deeply enough into the bedrock to provide adequate support. As a result, not only was the integrity of the well casing destroyed, but so was the bedrock that formed the seafloor. The rock was fractured in five places around the well. Oil and gas burst through the split casing, and broken bedrock of the seafloor and began to pour into the sea. A blowout had occurred, and, over the next 11 days, approximately 3 million gallons (11.4 million L) of oil flowed into the Pacific Ocean and was pushed by wind and currents into the pristine and biologically diverse waters of Santa Barbara's beaches, harbors, and channels.

The 800-mile- (1,288-km-) long slick tarred 35 miles (56 km) of beaches from Rincon Point to Goleta. Eventually shorelines as far south as Ana-

**Oil on Hobson Beach, Santa Barbara, California, after the blowout at Union Oil Company's undersea drilling platform several miles offshore, February 1969** (Vernon Merritt III/Time & Life Pictures/Getty Images)

capa Island's Frenchy's Cove, Santa Cruz, Santa Rosa, and the San Miguel islands were affected. Oil clogged the blowholes of dolphins, causing lung hemorrhages, and animals that ingested the oil, including more than 4,000 seabirds and an unknown number of seals, were poisoned. The bodies of the dead birds washed onto the shore for months after the blowout had been controlled.

### THE CLEANUP

Skimmer ships scrambled to collect the oil, while airplanes sprayed detergents (dispersants) on the surface of the water to break up the slick. Closer to shore, straw was used to absorb oil from isolated harbors and estuaries, and rocks were steam cleaned. This effort had the unfortunate side effect of parboiling the limpets and mussels attached to them. The dispersants used to break up the oil were found later to be almost as poisonous to birds and other marine life as the oil.

To control the blowout at the shattered well, drilling mud was pumped into the ruined steel casing at the rate of more than 60,000 gallons (227,125 L) per hour. After almost two weeks of round-the-clock work, the flow of oil was finally cut off and the well sealed with a thick cement plug. Residual amounts of oil and gas continued to escape from the cracks in the seafloor, and over the ensuing months all of the fractures were sealed with mud.

### THE AFTERMATH

The cleanup, payments to fishermen and local businesses, and lawsuit settlements cost Union Oil and its insurers several millions of dollars and forever changed the attitude of Californians about the wisdom of offshore oil exploration. The consequences of the Santa Barbara oil spill, however, spread far beyond California and changed the opinions of the nation.

Gaylord Nelson, a Democratic senator from Wisconsin, who was in California when the blowout occurred, toured the fouled beaches. He was so affected that he organized the first Earth Day the following year to raise public awareness of the human connection to the environment. A ban was placed on drilling for oil off the coasts of the United States. It lasted almost 20 years, and even today the exploration and development of potential offshore oil reserves on both the West and East Coasts meet with opposition, especially in California. Currently, there are only about 10 drilling platforms actively extracting the last of the oil from the known reserves in the Santa Maria and Santa Barbara–Ventura Basins. Although there were sales in the late 1990s

of offshore federal leaseholds to allow for additional exploration, the major oil companies have not shown much enthusiasm for pursuing their development.

Sensing the country's mood after the Santa Barbara oil spill, President Nixon signed the National Environmental Policy Act of 1969, which paved the way for the July 1970 establishment of the U.S. Environmental Protection Agency (EPA). Not surprisingly, federal and state regulations governing oil drilling procedures were toughened. In 1970, *Time* magazine called environmental quality the “issue of the year,” and a Gallup poll found that almost 70 percent of the American people considered air and water pollution to be serious problems. By 1972, the Clean Water Act and Clean Air Acts had been passed, and it became clear that environmentalism had established itself as a legitimate public policy issue.

**Savannah River Site Eastern South Carolina–Georgiaborder (1952–present) Water and Soil Pollution** In the 1950s, as part of the effort by the United States to develop and maintain its nuclear arsenal, a facility was built to purify and fabricate plutonium and tritium, some of the most technically challenging and dangerous work involved in the process. The Atomic Energy Commission (predecessor of the Department of Energy [DOE]) purchased 300

square miles (770 km<sup>2</sup>) of sparsely populated forest and swampland about 20 miles (32 km) southeast of Aiken, South Carolina, along the Savannah River, which separates Georgia from South Carolina. The Savannah River Site (SRS) is a secured, highly guarded facility with no permanent residents or housing facilities. The site is owned by the DOE and operated by a consortium of government contractors. There are about 16,000 employees at SRS and the annual budget is about \$1.5 billion.

### SRS FACILITIES

The SRS mission through the end of the cold war in about 1990 was to receive, store, and manufacture tritium and plutonium 239, the basic materials used in the assembly of nuclear weapons. More recently, SRS has refocused its activities to include the development and implementation of waste management solutions for the hazardous and nuclear residues present on the site. SRS is a massive industrial and research complex whose operations have left a legacy of severe environmental issues, and the DOE and its contractors are working aggressively to address them. There are numerous facilities that have these problems.

### POLLUTION AND REMEDIATION OF THE SITE

The primary constituents of concern released into the SRS environment are tritium, lead, trichloroethylene (TCE), and uranium. More than 500 waste units that require investigation, remediation, and closure in order to reduce risk and protect human health and the environment have been identified at SRS. These activities are being carried out under a variety of federal and state programs including CERCLA, RCRA, a Federal Facility Agreement (FFA), and a triparty agreement of the U.S. Environmental Protection Agency (EPA), the South Carolina Department of Health and Environmental Control, and the DOE. By 2005, SRS had closed almost 330 waste units, with another 48 units undergoing active remediation.

SRS operations contaminated groundwater around 15 waste disposal facilities. Extensive monitoring and remediation programs are tracking and cleaning up the contamination. No off-site wells have been contaminated by the migration of SRS groundwater. Although the Savannah River is used as a drinking water supply source for some residents downriver of SRS, the nearest intake is approximately 90 miles (145 km) downriver of the site. The river is also used for commercial and sport fishing, boating, and other recreational activities, but there are no known large-scale uses of the river

**Nuclear production facilities at Savannah River Site, Aiken, South Carolina, 2004** (DOE Photo)

for irrigation downstream of the facility. Groundwater remediation includes proper closure of waste sites to isolate them from the hydrogeologic environment and reduce the migration of contaminants into groundwater, as well as active recovery and treatment of contaminated water.

SRS is using a technique known as intrinsic bioremediation (also called monitored natural attenuation [MNA]) to address about 3,000 acres (1,214 ha) of wetlands, lake beds, and canals that have been contaminated with Cs-137 from discharges of reactor cooling water. The extremely large affected area makes removal of the contaminated soil impractical. Other types of remedial methods (e.g., stabilization or grouting) would essentially destroy a highly functioning wetland.

MNA is one of the more controversial approaches to site remediation. The EPA describes it as reliance on natural processes that, under favorable conditions, operate without human intervention to reduce the mass, toxicity, mobility, volume, or concentration of contaminants in the soil. These natural processes include not only biodegradation, which is the most important, but also a variety of other physiochemical processes, which include dispersion, dilution, sorption, and volatilization. Critics regard MNA as a no-action approach. For MNA to be effective, three conditions must be met at a site:

- The source of the contamination must be under control. MNA processes can be quickly overwhelmed by the continued influx of additional contaminant. The leaking tank or pipeline must be repaired or decommissioned and subsurface nonaqueous-phase liquid (NAPL) removed in order to give the relatively slow-acting biodegradation time to process the released material.

- Suitable microorganisms need to be present in sufficient quantities in the soil to degrade the contaminant. Given the ubiquitous nature of bacteria and their highly adaptive character, this is usually not a problem.
- Necessary electron acceptors and nutrients must be present in large enough amounts to allow the establishment and maintenance of a bacterial population that can degrade the contamination. This is why most sites

### POLLUTED AREAS AT THE SAVANNAH RIVER SITE

Facility	Description
Burial Grounds	A 200-acre (81-ha) area operated between 1952 and 1995 that is currently undergoing investigation and remedial plan development as part of the CERCLA program.
Consolidated Incinerator Facility	A 40,000-square-foot (3,716-m <sup>2</sup> ) incinerator was constructed in 1995 to incinerate low-level radioactive, hazardous, and mixed wastes safely.
Defense Waste Processing Facility (DWPF)	A 42,000-square-foot (3,902-m <sup>2</sup> ) structure that receives, treats, and immobilizes alkaline slurries of aqueous high-level waste into a durable, nonleachable borosilicate glass for disposal in a geological repository. Sixty-four canisters of vitrified high-level waste were processed successfully by this facility in 1996.
E-Area Vaults	These vaults, placed into service in 1994, cover approximately 100 acres (40 ha) and are used for the disposal of solid and low-level radioactive waste.
F Canyon	A 128,000-square-foot (11,892-m <sup>2</sup> ) facility used for the separation of plutonium and uranium and processing of plutonium and other materials. DOE is slowly decommissioning F Canyon.
FB Line	A 55,000-square-foot (5,110-m <sup>2</sup> ) plutonium separation facility constructed in 1953. Plutonium is currently stored in this building, awaiting stabilization prior to final disposal.
H Canyon and H Canyon Outside Facility*	A 403,000-square-foot (37,440-m <sup>2</sup> ) facility used for the separation of plutonium. This building will be used in processing of unneeded reactor fuels and in the purification of Pu-238 and other radioactive isotopes.
HB Line	A 28,000-square-foot (2,601-m <sup>2</sup> ) plutonium processing facility constructed in the 1980s and currently used for the storage of Pu-238 oxide product and scrap material. In 1991, five workers were contaminated by HB Line operations because of inadequate safety procedures. Operations resumed in January 1993 after extensive safety reviews caused by this and several other incidents.
In-Tank Processing Facility (ITP)	A 5,000-square-foot (465-m <sup>2</sup> ) nuclear waste processing facility intended to process high-level radioactive wastes and produce a decontaminated salt solution that is only slightly radioactive. This solution is processed further for disposal in the Saltstone facility.
Liquid Waste Handling Facilities	These facilities receive and store liquid radioactive waste, prepare the waste for processing, and transfer the prepared waste to DWPF and Saltstone for processing into stable, inert solids. SRS wastewater effluent also is treated within this operational center.
M Area Fabrication Facilities	These facilities are being used to decommission reactor materials in a safe, environmentally sound manner and to treat previously generated mixed low-level waste.
Naval Fuels	A 110,000-square-foot (10,291-m <sup>2</sup> ) enriched uranium fuel manufacturing facility that was constructed in 1987. This facility is currently not operational and is in a surveillance and maintenance mode. Process facilities are inactive and contain residual nuclear material resulting from previous operations. Procedures to shut down the facility have not yet been developed.
Old HB Line	A Pu-238 processing facility that was terminated in 1984. It produced Pu-238 oxide primarily for the space program as a heat source to be used in generating electricity for spacecraft in deep space. The new HB Line replaced it in 1984. In 1988, during decontamination activities related to decommissioning, four workers became contaminated during an emergency exiting of a highly contaminated area. This was due to the failure of a breathing-air compressor.

(continues)

**POLLUTED AREAS AT THE SAVANNAH RIVER SITE** *(continued)*

Facility	Description
PUFF	A 55,000-square-foot (5,110-m <sup>2</sup> ) facility containing Pu-238 hot cells that are currently in cold standby and serve as a storage area for nuclear material from weapons and nonweapon production.
Reactors (K, L, P, C, and R)	These are five heavy water nuclear materials production reactors that were used to generate plutonium, tritium, and miscellaneous isotopes. The K and L Reactors were used primarily for tritium production but are in safe shutdown mode. The P, C, and R Reactor facilities generated tritium as their primary mission but are currently used for isotope storage. They are in cold shutdown with no capability for restart.
Receiving Basin for Off-site Fuel	This is an operationally active spent fuel storage for research reactor fuels. It receives, handles, and stores irradiated nuclear fuel from off-site power and research reactors, from foreign reactors, and from on-site reactors. These materials are repackaged into containers and bundles for extended storage and/or shipment to on-site or off-site reprocessing facilities. This facility supports the SRS's technical role in controlling nuclear proliferation.
Saltstone	Includes the operations building and two concrete disposal vaults that are used to immobilize and dispose of decontaminated salt solutions. These solutions contain low-level radioactive compounds and heavy metal ions and are immobilized by mixing them with fly ash, cement, and slag. The slurry then is poured into large concrete vaults to harden. These vaults are the permanent disposal sites for the neutralized waste material.
Solid Waste Management Facility (SWMF)	The facility stores transuranic wastes, mixed wastes, and nonradioactive hazardous waste materials. It also disposes of low-level solid radioactive wastes generated from production of nuclear materials. It is made up of a series of burial grounds, vaults, and storage pads.
Storage of High-Level Radioactive Wastes	Tank farms at SRS store approximately 35 million gallons (132.5 million L) of liquid waste, constituting more than one-half (533 million ci) of DOE's high-level radioactive inventory. Unless properly managed, these wastes can pose radiological and environmental risks. The tank farm facilities consist of 51 USTs with a capacity of about 1 million gallons (3.8 million L) each. Two evaporators are used to concentrate the waste, and transfer pipelines, diversion boxes, pump pits, and associated vessels and pumps safely manage and transfer the tank contents. As tank contents are processed, low-level radioactive residues are sent to Saltstone, and high-level wastes are vitrified at DWPF for eventual shipment off-site.
Transuranic Waste Storage Pads	Nineteen storage pads occupying 114,000 square feet (10,591 m <sup>2</sup> ) have been in use since 1974. The containers on some pads are covered with soil, whereas others have weather-resistant enclosures. Eventually, the material on this pad will be assessed to determine whether it can be disposed of directly or treatment is necessary prior to disposal.
Tritium Facilities	These facilities provided tritium processing capabilities necessary for both nuclear weapons production and nonweapon (medical, research, etc.) uses. Three buildings make up this area, and they were used for such operations as extraction and purification, loading and unloading, and shipping and receiving.

**NOTES**

\* The building is called a canyon because of its long rectangular shape and hardened structure. Work inside the building is performed remotely, and employees are not exposed to radiation because of thick concrete walls.

fail. Bacteria quickly use up the oxygen, nitrogen, and other electron acceptors present in the subsurface, and biodegradation slows or stops until these materials are replenished. Even though other MNA pro-

cesses (dilution, dispersion, volatilization) can continue to operate, the time frames to reach cleanup goals may be unacceptably long without actively operating biodegradative processes.

An aggressive and comprehensive monitoring plan must be implemented at sites where MNA is the proposed remedial solution, and MNA processes must be periodically evaluated. This type of monitoring will alert the responsible party and regulatory agencies if hydrogeologic or geochemical conditions change to inhibit or adversely affect ongoing remedial processes.

### THE MNA SOLUTION

As a practical matter, most sites do not contain the necessary nutrients and electron acceptors in sufficient quantities to allow native bacterial populations to degrade the contaminants. Once more active remedial processes are under way, MNA may be appropriate for the outer edges of the plume or residual amounts of contamination.

Regulatory agencies and the public are justifiably suspicious when a responsible party presents a plan for an MNA-based remedy. To win acceptance for this type of approach, the responsible party must demonstrate a thorough understanding of site hydrogeology, biology, and geochemistry. The use of institutional property controls (zoning and land

use restrictions) may be necessary to ensure that land use at the site does not change in a manner that disrupts MNA processes or creates an unacceptable public health or environmental risk.

MNA is most frequently used at sites where soil or groundwater has been contaminated with pesticides, chlorinated solvents, gasoline, or polycyclic aromatic hydrocarbons (PAHs). MNA, however, works well on radionuclides. The decay of radionuclides is predictable and not subject to the availability of electron acceptors. All that is required is that the source is under control (i.e., no more releases are occurring) and that the radionuclides are not migrating. This is why MNA is being used in the wetlands at SRS.

Although the sediments present in the SRS wetlands contain some clay, not enough is present to ensure that the cesium will bind to that material and be less likely to migrate. The remedial engineers at SRS plan to seed the lake bottoms, wetlands, and former discharge canals with illite to help bind the cesium and prevent its migration or movement into the ecosystem. After placement of the illite, the area will be monitored while the cesium, which has a half-life of 30 years, slowly decays to levels that are not harmful to public health or the environment.

Burial of low-level radioactive solid waste at Savannah River Site, South Carolina, ca. 2001 (Peter Essick/Aurora Photos)

While MNA is an attractive remedial option, its use must be carefully considered. Time frames to achieve cleanup goals will be longer than for those of more active remedial measures. Long-term monitoring is necessary to ensure that contaminants are not moving because of changes to local geochemistry that may occur seasonally or over longer time frames. Institutional controls (restrictions on current and future land uses) are typically required components of an MNA plan along with the need for an extensive education and outreach program to gain public acceptance.

**Sea Empress oil spill Milford Haven, Wales (February 15, 1996)** *Water Pollution* One way oil is classified or graded is by the location where it occurs (e.g., West Texas or the North Sea), but the physical and chemical properties such as sulfur content, viscosity (resistance to flow), and specific gravity are used as well. "Sweet" oil usually is oil that contains very little sulfur. "Sour" oil, or gas is relatively high in hydrogen sulfide and requires additional refin-

ing to remove this undesirable constituent. "Light" oil has a low wax or paraffin concentration (long-chain alkane hydrocarbons) and can be pumped readily into tankers or pipelines. "Heavy" oil has a higher wax concentration and is more difficult to process and handle. Wax content is measured indirectly by evaluating the viscosity of the oil. A trade association called the American Petroleum Institute (API) has developed standardized methods to determine oil viscosity, which is a measure of specific gravity, or the weight of oil in comparison to water. Light crude oils have high API gravities. These types of oils tend to yield greater amounts of gasoline and require less refining than heavier oil. Oil that is sold as "West Texas Light Sweet crude" provides a frame of reference or benchmark price for brokers and companies that buy or market oil with similar characteristics from other parts of the world.

"North Sea Brent" oil is extracted from a number of fields in the North Sea and has long served as the benchmark against which the price for other grades of oil from this area and certain types of similar oils from Africa and the Middle East is set. As the supply of oil from the Brent fields began to decrease in the early 1990s, producers recognized the need to establish a new benchmark. "Forties Blend" gradually became an alternate benchmark oil replacing North Sea Brent. Forties Blend is a crude oil made up of both oil and gas liquids from 20 fields in the central part of the North Sea oil production zone. It is light oil (low viscosity) with a high percentage of volatile compounds and has an American Petroleum Industry (API) weight (specific gravity) of 40°. Forties Blend is also low-sulfur oil, generally containing about 0.35 percent sulfur or less.

### BACKGROUND

Much of the oil extracted from the sediments under the North Sea is pumped into supertankers and transported to Milford Haven, a port on the Pembrokeshire coast of Southwest Wales, United Kingdom. Almost the entire 170-mile- (273.6-km-) long coastline in this area is included in the Pembrokeshire Coast National Park, an important habitat for seabirds. The numerous and well-developed coves and estuaries along this coastline also serve as breeding grounds for a thriving marine fishery and support an extensive and diverse land and sea mammal population. Essential to the local economy, Milford Haven is a large natural harbor carved out of the rocky coastline by the confluence of several major rivers that drain into the sea. Milford Haven is the United Kingdom's major oil port and its fourth busiest port overall. Widely used by oil tankers, fer-

ries, the locally based commercial fishing fleet, as well as private pleasure craft, Milford Haven has a petroleum handling and processing infrastructure that recently underwent a \$4 billion expansion to increase its natural gas-handling capacity.

It was into this economically vital and exceptionally beautiful area that, in February 1996, the Liberian-owned and Russian-crewed *Sea Empress* steamed, fully loaded with 143,300 tons (130,000 metric tons) of Forties Blend oil. Built in Spain in 1993 as a single-hull Suezmax crude oil carrier, it was 900 feet (274.3 m) long, with a beam of 142 feet (43.2 m). Fully loaded, it could travel at almost 14 knots (26 km/h) powered by a 45,000-horsepower, No. 6 oil-fired engine driving a single screw. When the vessel arrived off Milford Haven, the Convention, Flag State (Liberia), and Class certificates were valid and up-to-date. Only three years old, the *Sea Empress* was in good mechanical condition. It had loaded the cargo at Hound Point, in the Firth of Forth (an offshore tanker loading and berthing facility in Scotland), and arrived about three miles (4.8 km) from the entrance to Milford Haven harbor on Thursday, February 15, 1996, just after 7:00 P.M.

### THE ACCIDENT AND SPILL

As required by most maritime regulations, a harbor pilot boarded the *Sea Empress* a few minutes after 7:00 P.M. to guide the ship the rest of the way through the harbor to its dock at a Texaco oil terminal. The weather was clear, with a stiff (10–20 mph [16–32 km/h]) west-northwesterly wind. The tide was retreating (ebbing), and there was a need to move the ship quickly to its berthing point so unloading could begin that evening. Water levels in the harbor would reach their lowest levels at around 9:30 P.M. Although the harbor pilot navigated the ship, the *Sea Empress* was still under the command of its captain, and, at about 7:45 P.M., the harbor pilot began directing the vessel toward the main entrance channel. Each course correction and speed requested by the harbor pilot was repeated to the helmsman and bridge crew in both English and Russian by the captain, whose command of these languages was later reported to be excellent. Unlike in the *Braer*, the level of effective communication between officers and crew was very good.

Commercial shipping into Milford Haven harbor is directed northward into one of two channels: the East Channel, which is the shallower of the two at about 30 feet (9.8 m), and the much deeper, although more narrow West Channel, with an average depth of about 50 feet (16.5 m). Because the draft of the fully loaded *Sea Empress* (i.e., the depth of the keel

below the water line) was just about 50 feet (17 m), the harbor pilot directed the ship toward the West Channel. The depth of the West Channel is maintained by regular dredging, an expensive and time-consuming process, so its approximately 1,200-foot (370-m) width is designed barely to accommodate the simultaneous passage (in opposite directions) of two very large crude carriers (VLCCs) such as the *Sea Empress*. The limits of the channel are marked by two buoys, Saint Ann's Light Buoy on the port (left) side, and Mid Channel Rocks Light Buoy, on the starboard (right) side. Fixed shoreline lights and buoys also are present to help direct ships to the midpoint or deepest part of the channel. The north-northeast-oriented West Channel is bounded on its western side by St. Ann's Head Shoals, where the sandy bottom of the channel is quite shallow. To the east of West Channel are the Middle Channel Rocks, an area where submerged boulders and shallow bed-rock form a hazard to navigation.

As the *Sea Empress* entered West Channel, the harbor pilot knew to keep the ship near the center of the waterway but had to include in his navigational plan the effects of the northwesterly wind, an outgoing southerly tide, and possibly an easterly cross-tide from St. Ann's Head that sometimes flowed at right angles to the point of approach. Requesting that the *Sea Empress's* speed be increased to its 14-knot (26-km/h) maneuvering pace, the harbor pilot could see the vessel was correctly aligned to enter the West Channel, about one mile (1.6 km) out. Adjusting the course slightly to the west, to account for the eastward-flowing tide, the *Sea Empress* was making 10 knots (18.5 km/h), and the harbor pilot, bridge crew, and captain thought all was going well. As the West Channel marker lights came into view about 1,500 feet (457 m) from its starting point, the harbor pilot realized that he had not corrected the course enough to account for the eastward-flowing tide and that the *Sea Empress* had been pushed east of the channel. He requested another course correction, but the ship responded too slowly, and, as the lights marking the Middle Channel Rocks passed by on the starboard side, a shuddering vibration ran throughout the ship, and then a popping sound was heard from below decks, accompanied by a strong smell of oil. At this same time, the helmsman reported that the vessel was not steering. The harbor pilot requested "full astern" and the captain ordered that both anchors be let go. He then radioed to request assistance from the four harbor tugs that had been standing by to help push the *Sea Empress* into its berth at Milford Haven.

The *Sea Empress* went aground near the southern entrance to the West Channel in an area known as

“the Pool.” This is a half-mile- (804-m-) wide, half-mile- (804-m-) long, 60-foot- (18-m-) deep section of the harbor that resembles the top of a funnel, with the West Channel forming the neck as it extends northward toward Milford Haven. Over the next three days, the *Sea Empress* bounced around the Pool like a pinball, pushed by gale-force winds, waves, currents, and tides, as tugs and salvage teams tried desperately to secure the vessel and unload its cargo.

Three cargo tanks and two ballast tanks on the *Sea Empress*’s starboard side had been breached when the ship skidded into the Middle Channel Rocks. It was listing 10 degrees to starboard and the pump room, the part of the ship where the cargo tank unloading controls were located, had flooded. By 4:30 A.M., it had been towed into the center of the Pool, the anchors reset, and four tugs were holding it steady. Another tanker pulled alongside to begin transfer of the *Sea Empress*’s cargo, and a salvage team was attempting to regain access to the pump room so that process could begin.

Weather conditions deteriorated during Friday afternoon and evening, and the tugs strained to hold the *Sea Empress* in position, even with the help of its own main engine. As the stormy weather turned into a full-fledged gale, it became increasingly more difficult to hold the *Sea Empress*’s stern toward the predominant direction of wind and waves, and port authority officials decided to turn the ship so that the bow pointed seaward. This required seven tugs, but by 4:00 P.M. Saturday, the turn was completed. The *Sea Empress*’s anchors, however, had been crossed and were now hopelessly tangled and unusable. An hour later, the *Sea Empress* began to move westward, pushed by the outgoing tide and a 40-knot (74-km/h) wind. The tugs tried valiantly to prevent the ship from drifting, but two towlines separated, and, despite its own engine’s straining, the *Sea Empress* went aground again, this time against the shoals off St. Ann’s Head. More tugs were called, and the salvage team decided to try to stabilize the *Sea Empress* on the shoal by flooding the undamaged ballast tanks. Those onboard were evacuated as wind speed increased to 60 knots (111 km/h) and two more tugs arrived on scene to attempt to hold the *Sea Empress* in place on the shoal by the bow. At 8:00 A.M. Sunday morning, however, the *Sea Empress* floated off the shoal on a rising tide and drifted eastward, smashing again into the Middle Channel Rocks. Forty minutes later, *Sea Empress* was on the move once more, this time coming to rest about 1.5 miles (2.4 km) northeast of the Middle Channel Rocks light, finally clear of the West Channel and at the northeast end of the Pool. At daylight, it drifted again, this time toward the

Middle Channel Rocks, and on early Monday, the ship went aground there at around 8:00 A.M. Salvage crews boarded the derelict to assess the damage and once again clear the pump room so that lightering could begin. At this point, the *Sea Empress* still held 132,000 tons (120,000 metric tons) of oil.

Later that afternoon (Monday), *Sea Empress* refloated and, taking five tugs along, moved westward across the main channel and went aground at St. Ann’s Head shortly after 6:00 P.M. Hearing noises that suggested a hull failure, the salvage crews were evacuated. The next morning, with *Sea Empress* having spent a rough night bumping and grinding against the shoal, salvage personnel and tugboat crews reported a significant amount of oil present in the water around the vessel.

Over the next 24 hours, salvage crews succeeded in gaining access to the pump room and were able to empty several of the ballast tanks to level off the badly listing ship. This, combined with the oil it was leaking, improving weather, and the use of 13 tugboats, allowed *Sea Empress* to be refloated at 6:00 P.M. on Wednesday evening and to be secured to a berth with mooring lines alongside Herbrandston Jetty just before 10:00 P.M. It had lost almost 79,000 tons (72,000 metric tons) of oil during the six-day ordeal into North Haven, more than half of the cargo. The North Sea Forties Blend oil that the *Sea Empress* was carrying is lightweight and volatile, oil that is more readily degraded by natural environmental processes (wind, waves, evaporation) than other types of oil. Despite the relative environmental friendliness of the oil, and even though the spill occurred in the dead of winter when habitat usage was low, the environmental consequences of the spill were still significant.

## AFTERMATH

More than 120 miles (200 km) of coastline was polluted, and of the 12,000 birds thought to have been present in nearby Pembrokeshire Coast National Park at the time of the disaster, up to 4,000 may have died and another 5,000 coated with oil. A ban on commercial fishing and shellfish collection, critically important to the local economy, was established by health authorities and extended over some 810 square miles (2,100 km<sup>2</sup>). Spawning rates for sea bass, the main commercial fish taken from the waters in and around North Haven, declined dramatically in 1996. Tourism, a \$300-million industry, was not affected very adversely, thanks in part to the more than 1,000 volunteers and workers who worked diligently for more than six weeks to remove more than 16,500 tons (15,000 metric tons) of emul-

sified oil and debris from accessible beaches and coves. Of the remaining oil, 40 percent evaporated or was blown out to sea by the same winds that had helped push *Sea Empress* around the North Haven Pool. About 2 percent of the oil was recovered by mechanical skimmers and booms, and almost 50 percent of it was degraded either by natural dispersion or aerially applied chemical dispersants. Only about 5 percent or so of the oil, 4,400–5,500 tons (4,000–5,000 metric tons), is thought to have washed up on beaches. Eighteen months after the spill, most coastlines were oil free and marine life was not showing visible signs of distress. In 2003, insurers paid out approximately \$60 million in claims, as compensation to local residents, for spill cleanup costs, and as compensation to Texaco for the value of the cargo.

The subsequent government inquiry into the cause of the wreck concluded that it was the harbor pilot's error in failing to correct adequately for the eastward-flowing tidal current present near the entrance to the West Channel. This error was, in part, related to inadequate training and a lack of a thorough understanding of current and tidal patterns within the channel. Since the *Sea Empress* oil spill, harbor pilot training regimens have improved and a comprehensive mapping and charting of harbor, channel, and Pool tidal patterns has been undertaken.

**selenium** Like many of the inorganic contaminants, selenium is a necessary nutrient in very small quantities but a dangerous health hazard at high levels. Selenium may be the most paradoxical of all of the elements that display this relation in that a little is believed to prevent cancer whereas a lot (in another compound) causes it. For this reason, there are recommendations from the Food and Drug Administration that a minimal amount of selenium should be ingested by all people, and regulations by the U.S. Environmental Protection Agency (EPA), Occupational Safety and Health Administration (OSHA), and the National Institute of Occupational Safety and Health (NIOSH) against excessive exposure. The lack of selenium has been tied to strokes in humans and "white muscle disease" in sheep. There are several cities in China, however, where the level of naturally occurring selenium is so high that residents suffer from selenosis. Selenium has been ranked as the 147th worst environmental threat of the 275 chemicals on the 2007 CERCLA Priority List of Hazardous Substances, and it has been found in 508 of the first 1,636 EPA-designated Superfund sites (National Priorities List) where it was tested. Although selenium does not commonly occur in high quantities, it can be concentrated by both anthropogenic and natural processes.

#### PROPERTIES, USE, AND PRODUCTION

Selenium is a naturally occurring inorganic element that is present throughout the environment in very small quantities. It occurs in three forms: noncrystalline gray metal, deep red to black powder, and red crystals. Its form depends upon the valence state and compound. It can occur in the  $-2$  valence state (hydrogen selenide, sodium selenide, dimethyl selenium, trimethyl selenium, and selenoamino acids); 0, or elemental selenium;  $+4$  valence state (selenium dioxide, selenious acid, and sodium selenite); and  $+6$  valence state (selenic acid and sodium selenate). Selenium was discovered in Sweden in 1817 as a contaminant. There are no high-selenium minerals in minable quantities. Instead, it has been produced as a by-product of copper refining and, more recently, of coal processing and burning.

Early uses of selenium were in rubber compounding, steel alloying, and production of rectifiers for electrical inversion. By 1970, silicon had replaced most selenium in rectifiers, and the leading use switched to a photoconductor in copiers. In the 1980s, however, this application declined. In the 1990s, it began being added to dietary supplements, though the volume of this application is relatively low. In the late 1990s, selenium was increasingly

used in plumbing brass to meet no-lead standards. Today, about one-third of total selenium is used to remove the green tint in glass caused by impurities and in architectural plate glass to reduce solar heat transmission. Cadmium sulfoselenide pigments consume about 20 percent to produce ruby-red color in plastics, ceramics, art glass, and other glasses, such as that used in traffic lights. Selenium is used in catalysts, in plating solutions to improve appearance and durability, in blasting caps and gun bluing, in rubber compounding chemicals, in electrolytic production of manganese to increase yields, and as an additive to improve machinability of copper, lead, steel, and brass alloys. Selenium is used as a human dietary supplement and in antidandruff shampoos (Selsun Blue). It also has strong photovoltaic capabilities and is used in solar panels and solar calculators. Agricultural uses are as a dietary supplement for livestock and as a fertilizer additive to enrich selenium-poor soils. In 1985, domestic production was reported at 429,515 pounds (195,234 kg). In 2006, the United States imported about 473 tons (430 metric tons) of selenium. The sources of selenium traditionally have been Belgium, 33 percent; Canada, 31 percent; Philippines, 15 percent; Germany, 6 percent; and others 15 percent.

### ENVIRONMENTAL RELEASE AND FATE

Small amounts of selenium are naturally present in rocks and soil everywhere, making it a non-point source pollutant. Selenium may also be a point source pollutant from a number of sources. It can be released from industry that uses selenium through leaks during transport, storage, and disposal. It may also be released from copper smelting, coal burning, petroleum refining, and coal mine effluence, among other sources. Selenium may be released into the air in compounds as particles from the burning of coal and oil or from volcanic eruptions. The particles primarily fall out or are washed out by precipitation close to the source, thereby increasing soil and surface water concentrations. Depending on the form, selenium either sinks in surface water if it is insoluble or dissolves into it if it is soluble. Insoluble selenium settles into the sediment and is very stable. Similarly, if released into the soil, insoluble selenium is immobile and remains a component of the soil indefinitely. Soluble selenium is highly mobile and leaches into the groundwater system. Selenium may also be taken up by plants. In acidic soil under anoxic conditions, uptake will be low; in alkaline soils, it may be significant.

According to the EPA Toxic Release Inventory, from 1987 to 1993 more than 1 million pounds (454,546 kg) of selenium was released to the environment from industry. The releases were primarily from copper smelting to land. The state with the highest release was Utah, followed distantly by Arizona, and even more distantly by Wisconsin, Indiana, and Texas. In 2005 alone, the release of selenium and selenium compounds in on-site disposal and releases totaled 1,483,064 pounds (674,120 kg), not including injection wells or landfills.

Selenium is generally toxic to aquatic life and has been known to be devastating to fish. Further, it bioaccumulates in muscle tissue, although it is not appreciably biomagnified. It is also toxic to waterbirds, which are exposed to selenium by eating tainted aquatic organisms.

### HEALTH EFFECTS FROM EXPOSURE

Although in low doses, selenium stimulates antibody production, makes antioxidants work effectively, helps regulate ion fluxes through membranes, and aids in the synthesis of coenzyme Q, in high doses, it can be harmful to human and animal health. Acute oral exposure can produce irritability, chills, muscle aches and pains, nausea, vomiting, abdominal pain, diarrhea, excess salivation, shallow breathing, tremors and convulsions, liver malfunction, pulmonary edema, coma, and death with increasing dosage. Laboratory animals also showed symptoms of liver and spleen congestion, kidney congestion and hemorrhage, altered blood chemistry, and pulmonary congestion and hemorrhage. Inhalation of selenium dust can cause irritation of the nose and throat, coughing, nosebleeds, loss of sense of smell, bronchial spasms, bronchitis, and chemical pneumonia, among the other symptoms common to ingestion. Dust can also cause skin and eye irritation. Chronic exposure to selenium results in loss of hair and nails, clubbing of the fingers, skin lesions, tooth decay, peripheral anesthesia, pain in the extremities, hyperreflexia of the tendons, numbness, convulsions, paralysis, and motor disturbances. Laboratory animals showed loss of hair, malformed hooves, rough hair coat, impaired vision, paralysis, liver and kidney damage, and immune system damage. Selenium has also been shown to have negative effects on the reproductive system including decreased rates of conception, increased rates of fetal absorption, reduced birth weights, and birth defects including severe skeletal abnormalities.

The EPA designated selenium and selenious acid in group D, not classifiable as a human carcinogen; selenium sulfide was designated in group B2, as a probable human carcinogen. Laboratory studies showed significant increases in the incidence of bronchial and liver cancer in laboratory animals that resulted from exposure to selenium sulfide.

### REGULATIONS ON HUMAN EXPOSURE

As a result of these adverse health effects and the threat to public health, federal regulatory agencies have established limits on selenium exposure. The EPA limits selenium in drinking water to 50 parts per billion (ppb) under the Safe Drinking Water Act. They further require the reporting of the release of 10 pounds (4.5 kg) or more of selenium sulfide. OSHA set a permissible exposure limit (PEL) for selenium of 0.2 mg per cubic meter of air over an eight-hour-day, 40-hour workweek. NIOSH set the same exposure limit (REL) of 0.2 mg per cubic meter of air over a 10-hour day. The immediately dangerous to life and health designation is for levels of 2 ppm for selenium hexafluoride and 1 mg per cubic meter for all other selenium compounds. The NIOSH 1972–74 National Occupational Hazard Survey estimated that 8,500 workers were exposed to selenium; the NIOSH 1982–83 National Occupational Exposure Survey estimated that 27,800 workers were exposed to selenium. In contrast to the restrictions to exposure, the Food and Drug Administration recommends a minimal intake of selenium of 70 micrograms per day for adults.

### Seveso dioxin release Meda, Italy (July 10, 1976) Air Pollution

Meda is a small town about nine miles (15 km) north of Milan, near Italy's border with Switzerland. Tourists and townspeople regularly take leisurely walks along the wooded paths of the picturesque Seveso Oak Forest Park. Underneath the bike paths and pedestrian walkways are two large concrete tanks full of the poisonous residue of one of the most dangerous chemical spills since the beginning of the Industrial Revolution.

Since the early 1900s, a company named the Industrie Chimiche Meda Societa Azionaria (ICMESA) had been manufacturing chemicals inside a series of brick buildings just outside Meda. These products were shipped to chemical plants throughout Italy and Europe for use in the formulation of finished goods, including pesticides and flame retardants. Materials processed at the plant included 2,4,5-trichlorophenol, used in the production of pesticides, and a nuisance chemical by-product of pesticide manufacture, 2,3,7,8-tetrachloro-dibenzo-p-dioxin, more commonly known as TCDD, or dioxin.

### THE POLLUTION RELEASE

Saturday, July 10, 1976, started routinely at ICMESA, but inside an enclosed tank in Building B problems were beginning. At around 12:30 p.m., a mix of chemicals that had been left in the tank in midproduction cycle untended through the weekend started to react exothermically. Eventually, pressure built up inside the tank and caused a rupture disk within a safety valve to fail, and a plume of toxic gas, consisting primarily of steam and containing 2,4,5-trichlorophenol and dioxin, was released. It formed a towering cloud extending up to 150 feet (46 m) into the atmosphere. No workers were present inside the building, and the release was unnoticed for most of the day. The cause of the runaway reaction that led to the release and the reason that the chemicals were left unattended inside the tank in the middle of a production cycle have never been explained.

Slowly dispersed by a gentle southwest wind, the vaporized chemicals settled over the farms and homes of the nearby town of Seveso, 1.8 miles (3 km)

away. Although the amount of chemicals released into the atmosphere from the ICMESA plant has been difficult to confirm, most researchers think that about 1,400 pounds (636 kg) escaped, which included a quantity of dioxin ranging from 0.05 to 20 pounds (23 g–9.1 kg) or more.

Unsubstantiated reports surfaced that ICMESA was involved in chemical weapons research for the Italian government or the North Atlantic Treaty Organization (NATO) and this was why such large amounts of dioxin were present at the plant. Later investigations found no evidence to support these rumors.

### THE RESPONSE AND AFTERMATH

By today's standards, the response of the company and the Italian government over the next few days after this release seems criminally negligent. It was not until the following day that ICMESA managers informed the local authorities that a "cloud of

herbicide that causes harm to agriculture" had been released and suggested that local residents be notified not to eat vegetables from their gardens. By July 14, it started to become clear that the nonchalance of the company's announcement was out of proportion to the potential health effects of the release. Small animals began to die, and children started developing rashes.

Five days after the release, the local authorities finally began to suspect that something was seriously wrong. The deputy health officer declared a 30-acre (12-ha) zone downwind of the plant contaminated and ordered some 200 residents to evacuate. Under pressure from their parent company, the multinational pharmaceutical corporation Hoffman LaRoche, ICMESA officials grudgingly agreed to have a doctor examine workers who might have been exposed to the toxic gas. Later that day, ICMESA managers held a meeting with the mayor, and they produced a few maps showing where the gas cloud might have settled but otherwise did not

Warning signs being posted around Seveso, Italy, after release of a pesticide cloud containing dioxin, 1976 (© Hulton-Deutsch Collection/CORBIS)

offer much in the way of real information. ICMESA knew at this meeting that the material released contained dioxin, but they would not inform local officials of this for another nine days.

As the dioxin and other chemicals began to be incorporated into the local environment, residents began to notice that rabbits, often held as pets, commercially bred, or even seen in fields, were dying in alarming numbers. More importantly, the number of children who had burnlike skin lesions began to increase. Eventually, 13 would require hospitalization and emergency treatment. Within two weeks of the release, approximately 3,300 animals died. With fears over the extent of contamination spreading, the government ordered the slaughter of 78,000 farm animals, pets, and livestock.

By the end of July, the situation had overwhelmed local authorities, and the national government had mobilized the army. An additional 800 people were forcibly evacuated, and the contaminated and quarantined zone eventually extended to more than 3,700 acres (1,500 ha). More than 220,000 people from the five municipalities of Lentate sul Seveso, Seregno, Varedo, Muggiò, and Nova Milanese were affected, and almost 40,000 were seriously exposed. As is often the case in forced evacuations, especially those connected to environmental disasters where the risks often are not obvious and are difficult to explain, many relocated families returned to their homes in October and December 1976 before being once again made to leave by local authorities.

In late July, the Italian press finally recognized the severity of the situation, and banner headlines began to appear in major newspapers. ICMESA plant buildings were ordered closed, and company chemists confirmed that dioxin had been detected in soil and vegetation samples downwind of the plant. They also offered a map indicating where dioxin was found in the samples they had collected. Workers at the factory started to accuse governmental authorities of withholding information. Pregnant women from the affected areas were advised that existing laws against abortion had been waived and pregnancies that would be psychologically traumatic for the mother could be legally terminated. ICMESA's technical and production directors were arrested.

The most obvious near-term health affects of the release, 193 cases of skin rashes, were eventually reported and diagnosed as chloracne, a severe dermal disorder usually associated with exposure to high doses of chlorine and halogenated aromatic hydrocarbons. Its symptoms include an acnelike eruption of cysts, blackheads, and pustules on the cheeks, behind the ears, in the armpits, and around

the groin. The more severe cases did not clear up for years and left permanent scars.

By early August, the Italian government had committed more than \$80 million to the relief effort. Later in the month, Hoffman LaRoche agreed to pay for relocation, medical, and cleanup expenses. The regional government established the Giovanardi Commission to oversee, coordinate, and direct governmental response activities, including medical and epidemiological studies.

### THE CLEANUP

In September, with the public health crisis basically under control, the government and ICMESA turned their full attention to the cleanup. Jobs were found for the displaced ICMESA workers, and the remaining raw materials and chemicals were removed from the factory for disposal. By January 1977, cleanup efforts were under way in earnest, with the goal of making the area safe for reoccupancy and restoring it to productive agricultural use. Schools were decontaminated and water quality studies undertaken. Leaf litter, grass, and unharvested agricultural produce were collected and stored for later disposal. Epidemiological and medical monitoring programs were established to study the effects of the dioxin release on unborn children and cancer rates and death rates in the general population, as well as to monitor the health of workers at the ICMESA plant.

Even with all of their relief efforts, many of the residents and workers still thought they had been mistreated and ignored by both the government and ICMESA. In September, the director of the Seveso Health Department was shot in both legs. In 1980, ICMESA's production director at the time of the accident was shot and killed.

### LONG-TERM EFFECTS

The public health effects of the Seveso dioxin release were first documented in studies that began in 1977 and are continuing to this day. Chloracne was one effect that was clearly related to the disaster. Longer-term studies of liver function, immune function, neurologic impairment, and reproductive effects have been less conclusive. Excess mortality rate from cardiovascular and respiratory diseases was found among the survivors, possibly related to a combination of both chemical exposure and stress associated with the personal upheaval the accident caused to many individuals and families. The number of diabetes cases also increased. Cancer and cancer mortality rose, especially those associated with the

gastrointestinal system and lymphatic and hematopoietic tissue. These results, however, could not be definitively connected to the accident. The study is continuing in an attempt to overcome logistical limitations, such as limited individual exposure data, short latency period, and small population size for certain cancer types, and to explore new research paths.

One potential impact of the release that received widespread media coverage is that for the first seven years after the accident, more of the babies born to parents who had been exposed were females, 46 females compared to only 28 males. Typically, the numbers of female and male births are about the same. This change in the sex ratio was also reported for workers exposed to dioxin from an incinerator in Japan.

In October 1977, 500 evacuees were allowed to return to their new homes, after the old ones had been demolished. By 1985, most reclamation had been completed, and the ICMESA property had been converted to a park, the Seveso Oak Forest. In 1995, almost 20 years after the release, the cleanup was officially declared complete, all the residents had returned, and the final contaminated area was released for cultivation.

Deeply buried below the Seveso Oak Forest are two large concrete tanks into which has been placed 40 cm (16 inches) of TCDD-polluted topsoil, scraped off farms, roads, and backyards. Also resting quietly inside the tanks are the carcasses of the contaminated animals, the ICMESA factory, as well as the remains of the other buildings covered by chemical fallout after the release. Groundwater from these two basins seeps into another tank, where it is treated and released. This system is constantly monitored and will be for at least the next century.

**sewage treatment plants** One of the main problems that face society is disposal of wastewater. In many areas, it is handled on an individual level using a septic system. Sewage that is removed from homes and businesses through a public sewer system by law must be treated before it can be released. Before such laws were passed, water was withdrawn from rivers on the upstream side of cities and towns, and raw sewage was dumped into rivers just downstream of them. This practice resulted in highly polluted rivers and rampant disease including plagues, causing many deaths. It was because of these problems that regulations were established to purify the water and improve public health. In a plant, wastewater is treated by using primary treatment, secondary treatment, and advanced treatment.

## SEPTIC SYSTEMS

In America, septic systems are the most common form of waste disposal in areas without sewers. It is estimated that roughly one-third of sewage is disposed of by septic systems. In these systems, sewage is removed from the home through a system of drainage pipes, which coalesce into a single master drain. The sewage first flows into a settling tank, where solids settle to the bottom and are thereby separated from the liquids. The liquids either are discharged into leach beds or drain into dry wells. The sewage enters the leach beds through perforated drain tiles and percolates into the soil below. The dry wells are vertical perforated culverts beneath the settling tank, where fluids may percolate. The idea is that the liquid waste will be purified by percolation through soil before entering the water table. In many areas under certain conditions of soil and home density, the systems perform acceptably. In many other areas, they produce contaminant plumes in shallow unconfined aquifers that can affect adjacent wells or surface water bodies. With time, the settling tanks fill with solids and must be pumped out and into a truck from a septic service.

These systems can handle only a small amount of wastewater at any given time and can easily fail if overwhelmed. Output from these systems is rarely

Settling tanks are used to allow treated water to clarify through solids sinking to the bottom of the vessel, where they can be removed for further treatment and disposal. (Chris Knapton/Photo Researchers, Inc.)

monitored, and it can have a negative impact on water quality in an area, leading to many lawsuits. It is for this reason that public sewers that transmit the sewage to wastewater treatment plants are used on an ever-increasing basis.

### WASTEWATER PREPRIMARY TREATMENT

Typically, there is a preprimary treatment performed on the wastewater to screen out, grind up, or sepa-

rate debris. Debris may include sticks, rags, large food particles, sand, gravel, and toys, depending upon the source. This debris is removed to protect the pumping and other equipment in the treatment plant. Treatment equipment includes bar screens and grit chambers, and comminutors, which are large versions of garbage disposals, are used as the wastewater first enters a treatment plant to remove debris. In some instances, the wastewater may be first sent to a settling lagoon before processing.

### PRIMARY TREATMENT OF WASTEWATER

Primary treatment involves screening and sedimentation. Screening is done by passing the wastewater through a filter or screen, which removes grit including sand and stones and other large particles. The rest of the particulate is allowed to settle out of the wastewater in a tank to form an organic-rich mudlike sediment, called sludge, which is then piped to the digester. The remaining wastewater has had about 30–40 percent of the pollutants removed and is pumped into the secondary treatment section.

### SECONDARY TREATMENT OF WASTEWATER

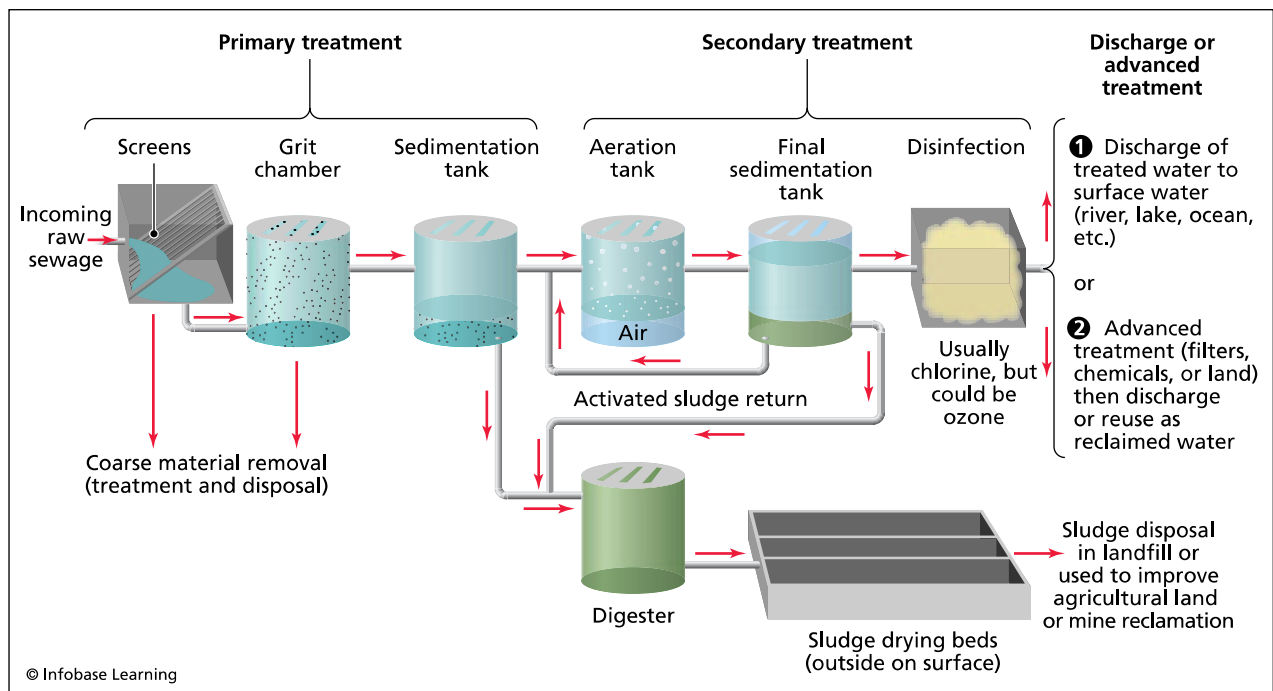

Secondary treatment begins with the pumping of wastewater into an aeration tank, where air is pumped in and aerobic bacteria break down most of the remaining organic material. Wastewater is pumped to the final sedimentation tank, where the remaining sludge settles out. Most of that sludge is also pumped to the digester. The remaining sludge is sent back to the aeration tank to act as a bacterial starter for the new sludge. The sludge in the digester undergoes further decomposition through the actions of anaerobic bacteria. The processes in the digester further reduce the organic component but also have as a by-product methane gas, which can be collected and used as fuel. About 90 percent

of the organic component of the waste, termed biochemical oxygen demand (BOD), is removed by the time it has passed through secondary treatment. The waste, however, still contains some nutrients such as nitrogen, phosphorus, and heavy metal, as well as manufactured compounds such as solvents and pesticides. The final stage of secondary treatment is disinfection of the wastewater, typically using chlorine but also using ozone or even ultraviolet radiation, in some cases. Usually, at this point most of the wastewater is returned to surface waters, though, in some areas, it is pumped into injection wells. The remainder can be sent on for advanced treatment.

### ADVANCED TREATMENT OF WASTEWATER

Advanced treatment is undertaken to remove nutrients, heavy metals, and other chemicals of interest. This step is only taken if high-quality treated wastewater is needed for uses such as wildlife habitats or irrigation for crops, parks, and golf courses. This treatment usually involves sand and carbon filters and raises the removal of pollutants from the wastewater to 95 percent. Wastewater that has had advanced treatment is referred to as reclaimed water.

**Sierra Club** The Sierra Club is America's oldest and best established citizen environmental organization. It is also the most credible and well respected of the environmental organizations and, as such, is most commonly solicited for opinions and information for environmental issues. The Sierra Club has evolved over the years from an organization that was mainly concerned with land preservation and outdoor excursions for its members to one that also includes a significant component of environmental activism. The current mission statement of the Sierra Club is as follows:

1. Explore, enjoy and protect the wild places of the Earth.
2. Practice and promote the responsible use of the Earth's ecosystems and resources.
3. Educate and enlist humanity to protect and restore the quality of the natural and human environment.
4. Use all lawful means to carry out these objectives.

Many of the goals of the Sierra Club and issues it addresses are the same as those of Greenpeace International, but they are, in general, not nearly as radical or outwardly confrontational. The Sierra Club engages in protests, legislative action, and legal action in an organized and effective manner to carry out the serious goals of its mission. It is, however, a recreational organization, and that remains the common thread that unites the group.

### HISTORY OF THE CLUB

The Sierra Club was founded by John Muir and 182 charter members on May 28, 1892, in San Francisco, California. The main effort for the club was to prevent the reduction in size of Yosemite National Park. John Muir would serve as president from 1892 until 1914. By 1899, the club had more than 350 members and was able to influence the establishment of Mount Rainier National Park. In 1901, the Sierra Club had its first outing, a tradition that would become the trademark of the organization. Naturally, the club chose to visit Yosemite National Park. By 1907, the club was dealing directly with the U.S. secretary of the interior, in this case, to oppose the damming of the Hetch Hetchy Valley in California. The following year, membership reached 1,000 people. In 1911, the Sierra Club had gained enough influence that the Devil's Postpile National Monument was established primarily through their efforts. The same year, the first local chapter of the Sierra Club, the Angeles chapter, was established in Southern California. In 1916, the club helped to establish the U.S. National Park Service, and the Sierra Club member Stephen Mather was appointed the director. In 1927, after lengthy efforts by the club, California established a state park commission and named the Sierra Club secretary, William Colby, the first chairman. By 1930, the club membership had surpassed 2,500. In 1934, another famous American, Ansel Adams, joined the board of directors and became almost synonymous with the club. He remained on the board until 1971. With time, the influence of the club grew stronger, as did its reputation. It developed enough influence actually to oppose efforts by the U.S. government and prevail. In 1943, the Sierra Club successfully defended the Jack-

son Hole National Monument against government officials who opposed it. In 1949, many years of effort came to fruition when both the secretary of the interior and the secretary of the army rejected the Glacier View Dam project in Glacier National Park, which they had opposed. In 1950, the Atlantic chapter of the Sierra Club was established. It was the first chapter outside the state of California and comprised 18 states and the District of Columbia.

David Brower, another pillar of the Sierra Club, became its first executive director in 1952, a position he occupied until 1969. During this time, many projects were undertaken, many of which changed the shape of American national parks. A complicated battle at that time was the saving of Dinosaur National Monument almost completely through club efforts. In 1956, membership reached 10,000, and by 1960 it was 16,000. A major change in emphasis for the club occurred in 1963, when an office was opened in Washington, D.C., specifically to address elected officials. Perhaps, in part, as a result, the U.S. Congress passed the Wilderness Act in 1964 as the first wilderness protection legislation in the world. This was considered a great victory for the Sierra Club because it had lobbied so hard for its passage. The Sierra Club underwent great expansion through the 1960s, including the establishment of a Sierra Club of Canada in 1963. By 1970, there were 114,000 members and club chapters in all 50 states. With the increased popularity and resources, the club began filing lawsuits to help protect the environment. In 1969, it won a suit to stop pollution in Lake Superior, thus shifting the direction toward antipollution, as well as land preservation.

The increased activism in pollution reduction corresponded with the lobbying, passage, and enactment of the National Environmental Policy Act, which established the U.S. Environmental Protection Agency. The shifting priorities of the nation allowed the Sierra Club to shift its policies and efforts toward pollution reduction. In 1972, the Sierra Club filed a lawsuit that led to a ban on domestic use of dichlorodiphenyltrichloroethane (DDT). It led an effort that defeated legislation to overhaul public land laws to favor commodity interests. It led efforts that would ultimately result in the passage of the Water Pollution Control Act over a veto of the then-president Nixon. In 1975, a Sierra Club lawsuit expanded the National Environmental Policy Act to cover actions of the United States involving marine and international situations. In 1977, the club persuaded the then-president Jimmy Carter to route the national gas pipeline around the Arctic National Wildlife Refuge in Alaska. In addition to these examples of sweeping

legislative changes, there were numerous actions on the regional scale to increase holdings of national and local wildland parks and preserves, prevent the damming and alteration of rivers and wetlands, and reduce harvesting of commodities from national lands.

By 1981, membership in the Sierra Club had reached 200,000, and by the next year, it was 325,000. Part of the reason for the increased interest was the very public conflict between the then-secretary of the interior James Watt and environmentalists from all sectors, led by the Sierra Club. Much of the beginning of the 1980s was spent attempting to preserve the victories of previous decades. Efforts to reduce the standards of the Clean Air Act, selling of public lands to industry, and allowing of energy exploration in wilderness areas were largely repelled but at no small cost to the resources of the club. In 1982, they attempted to influence legislation by actively participating in the 170 midterm congressional contests as well as in 150 state and local contests. In the end, 80 percent of the Sierra Club-backed candidates won the elections, and this may have been a contributing factor in the resignation of James Watt the following year.

After this regrouping, the Sierra Club became even more involved in influencing legislative decision making, although the tide of support gained through earlier work was self-sustaining in many cases. A Sierra Club lawsuit forced the EPA to regulate the release of radioactive pollutants in 1984. In 1985, the club worked diligently to help ensure the reauthorization of a strengthened Superfund and Clean Water Act. In 1990, a strong effort by the Sierra Club helped to enact a strengthened Clean Air Act in spite of a threatened veto by then-president George H. W. Bush. In 1993, the Colorado wilderness bill was enacted thanks to a decade-long club campaign, as was the California Desert Protection Act in 1994 after an eight-year fight. In 1996, the Sierra Club won a Clean Air lawsuit in Colorado that resulted in a record settlement for a suit filed by private citizens. It required \$145 million to install emission controls in power plants and \$4 million in penalties to clean air pollution in the Mount Zirkel Wilderness.

### CURRENT PRIORITIES AND ACTIVITIES

The Sierra Club currently has more than 1.3 million members and is as active as ever. They list several areas as their current priorities and initiatives for at least the next few years. These priority campaigns include:

1. Stop sprawl and revitalize communities.
2. Protect and restore wildlands.

3. Protect and restore national forests by ending commercial logging on federal public lands.
4. Defend the Clean Water Act, protect streams and wetlands and reduce pollution from corporate animal factories.
5. Curb global warming and promote safe, clean energy.
6. Fight for “clean, green and responsible” trade policy.
7. Promote family planning and work to stabilize world population.
8. Protect the human rights of environmental activists worldwide.

Many of these priorities have been the same for decades and some for most of the history of the club. Priorities 4, 5, and 6 deal directly with pollution but are similar to the actions of other environmental groups. By virtue of its size and reputation, the Sierra Club may be able to encourage improvement in these areas better than most other organizations, but these are all tall tasks with no easy solution.

Some controversy surrounds priority 7. The Sierra Club is of the opinion that the runaway overpopulation of the Earth by humans is significantly degrading the environment. The population should be stabilized and ultimately reduced if we ever hope to achieve sustainability. In the mid-1990s, some of the members of the Sierra Club were in favor of controlling the population of the United States as a first step toward this goal. In order to stabilize the U.S. population, immigration would need to be controlled, since much of the growth results from that sector. A splinter group was formed called the Sierrans for U.S. Population Stabilization but was opposed by the vast majority of the membership, who wished to remain neutral on the issue of immigration. The idea surfaced several times and was even a ballot issue, but it never amounted to much and appears to have been dropped.

**soil** Soil is one of our most precious resources, and yet it is regarded with disdain by most humans. Many common sayings in many languages bear this out. The vast majority of our food supply either is grown directly in soil or survives only because it

feeds on the food grown in the soil. Were it not for soil, very little life would be possible outside the oceans.

By definition, soil is all unconsolidated material lying above bedrock and formed by the surficial processes of the Earth. It is composed of rock in various degrees of mechanical and chemical breakdown, organic detritus in various forms, microorganisms of various forms, and various forms of materials added by natural and artificial processes. With such a cumbersome definition, it is no wonder that the classification of soils takes on various forms. There are a textural/chemical classification, a classification by structural development, and a classification by regional associations.

## SOIL MATERIAL CLASSIFICATION

There is a simple classification of soil composition based upon the components of clay, silt, and sand. This system is displayed on a ternary graphical diagram in which there are subdivisions into compositional fields with some basic names. Either the soil is composed of one of the three end members (clay, silt, and sand), or it is composed of some mix of two or three, called loam. Most soil is some form of loam. Depending upon the composition of the clay, the soil name can be further modified. There are numerous types of clays; chemical analysis is required to identify them in most cases. These clays can adsorb certain elements, so they can be important sources of nutrients or dangerously polluted.

## SOIL HORIZONS

Soils also form characteristic profiles if they are residual or formed from the weathering of the underlying bedrock. In this case, they develop horizons. At the surface, the O horizon is completely organic and composed of decaying leaf litter. It is sometimes called humus and is almost always home to plants and animals. The A horizon is the next down and commonly called topsoil. It, too, is organic-rich but also contains clays and other evidence of decayed rock. It is home to much biologic activity. The underlying B horizon is commonly referred to as subsoil. Unlike the overlying horizons, which are dark, the B horizon is generally tan and clay-rich. It commonly contains fragments of partially decayed rock and only roots of trees and other large plants. There are certain animals that burrow into the subsoil but far fewer than in the upper horizons. The C horizon is composed primarily of fragments of bedrock in various stages of decomposition.

The development of each of the horizons depends upon the local environment. In arid areas, there is little vegetation, and consequently the O horizon is typically absent or poorly developed at best. Glaciers removed most of the soil during the last ice age. A result is that the O horizon may sit directly on bedrock or on glacial sediments in many areas, such as the northern United States, with minimal A, B, or C horizons. In old, deeply weathered terranes such as the southeastern United States, the A, B, and C horizons may be quite thick, 50 feet (15 m) or more. The soil retains the layering and structure of the parent rock, but all of the minerals are altered to clay, iron oxides, and relict quartz. This material is called saprolite.

## SOIL STRUCTURE

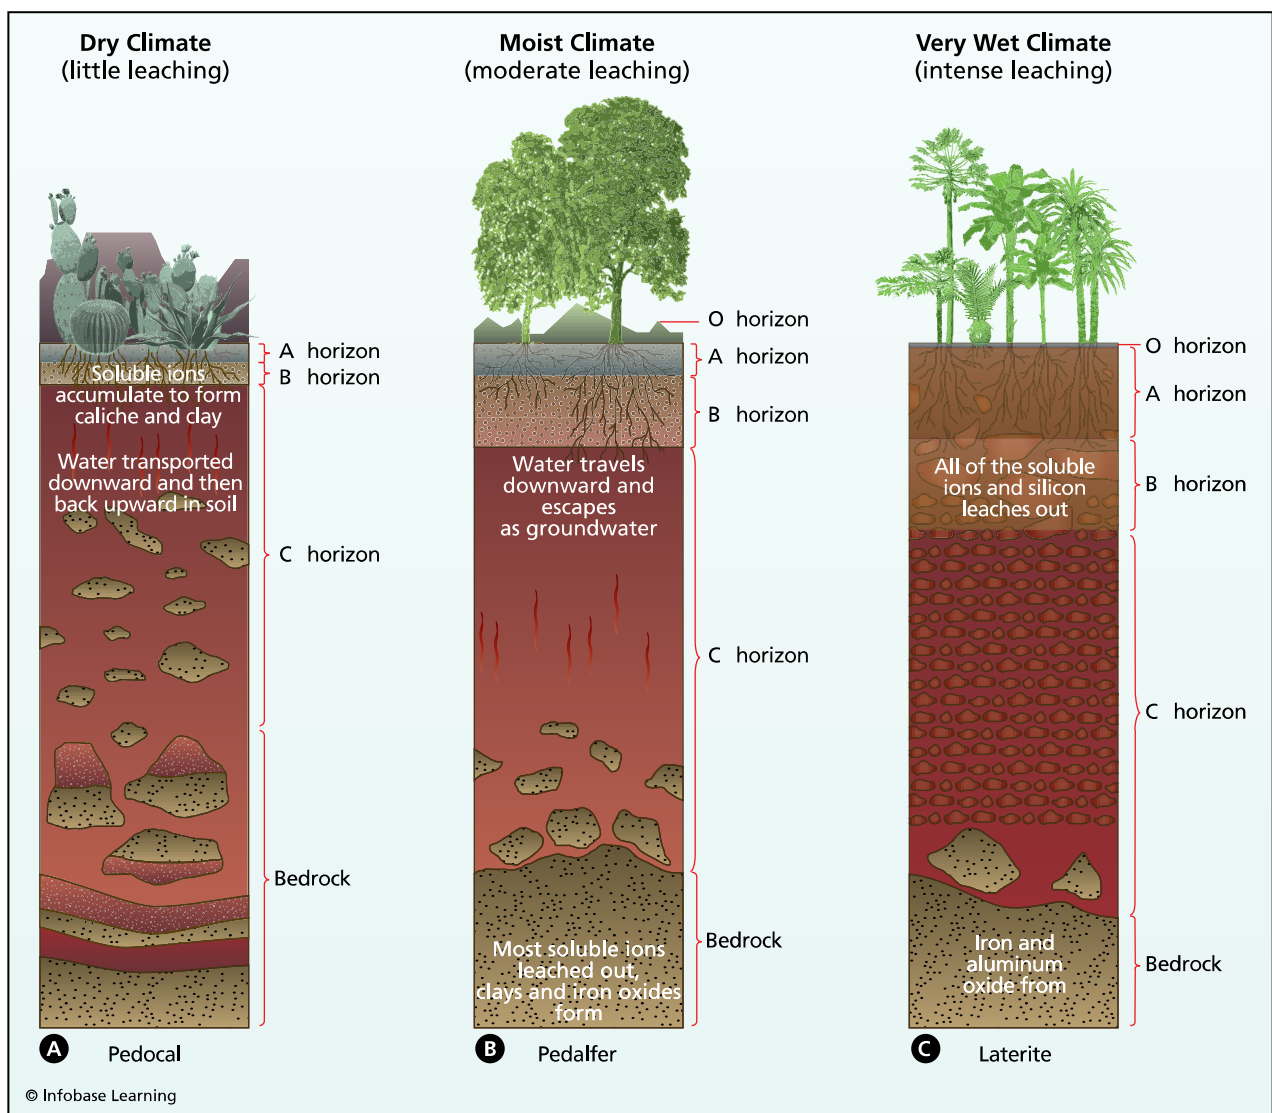

There are five recognized categories of soil structure based upon the shape with which they break apart under natural conditions. Some soils have no structure and are massive, as are many soils that are worked by humans. The five types are described as follows:

1. *Platy* soil structure means that soil breaks relatively easily into flat, generally horizontal, plate-like aggregates. The plates are lenticular-shaped in some areas and generally impede infiltration of water and downward growth of roots. Platy structure is found in B and C horizons that have

**Illustration of a standard soil profile showing the soil horizons. In the top horizon, O is organic, but the other horizons are just labeled for their order, top to bottom. Not all horizons are present in all soil profiles and their thicknesses can be highly variable.**

- been extensively leached or flattened by animals or machinery.
2. *Prismatic* soil structure is characterized by aggregates that are separated by flat to rounded vertical faces and rather indistinct prism-shaped tops. These structures are common in B horizons, where there are extensive wetting and drying, freezing and thawing, or strong downward movement of water or growth of roots.
  3. *Columnar* soil structure is similar to prismatic structure, but the vertical cracks are deeper and the prism-shaped tops are more distinct. The structure is relatively pervasive and gives the soil a columned or palisades look.
  4. *Blocky* soil structure occurs when the aggregates are relatively equidimensional with flat to slightly curved cracks or edges. They may be angular if the edges are straight or subangular if they are somewhat curved. They are common in areas of high swelling clay content.
  5. *Granular* soil structure occurs where the aggregates are rounded and do not fit together as most of the other categories do. Mechanical working tends to reduce the size of the aggregate.

**Representative soil horizons for three common types:** Pedocals are rich in calcite (cal) and common in dry areas such as the southwestern United States (A); pedalfers are rich in aluminum (Al) and iron (Fe) and are common in temperate areas with plentiful rainfall like the eastern United States (B); and laterites are very rich in aluminum and are common in tropical climates with plentiful rainfall (C).

**Map of North America showing the distribution of general soil types (see text for description of the soil types). A soil map of specific areas would be needed to determine local soils.**

gates. They drain well and can accumulate organic material, making them relatively fertile. They are common in rich grasslands and many tilled areas.

### SOIL TYPES

Soil in the United States is also traditionally classified into types primarily by general compositional characteristics developed by long-term weathering.

In this traditional classification system, the most common are pedalfers, pedocals, and laterites:

*Pedalfers.* Soils that are rich in aluminum and iron. They are common in temperate areas where there are significant rainfall and vegetation. Acid from decaying vegetation dissolves out most minerals, especially those rich in calcium and alkalines. These soils are common in the northeastern United States.

*Pedocals.* Soils that are rich in calcium. They occur in very dry climates that are typically hot.

They develop hard pans that are like cement in some cases and commonly contain caliche. Pedocals are common in the southwestern United States.

*Laterites.* Soils that are extremely rich in aluminum. They are common in very rainy tropical areas, where weathering is very deep. Acids from decaying vegetation remove everything but aluminum and some clay. They can develop into bauxite, which is mined for aluminum.

The modern system of soil classification in the United States is more complex and comprehensive to take into account the great variations in texture and composition. This U.S. Comprehensive Soil Classification System includes 12 major orders of soil based upon both environment and physical character, although many are very minor. There are huge numbers of suborders of each order and some 19,000 soil series beneath them. There are also numerous other world classifications that are not included in the American system and are described as follows:

*Alfisol.* A young soil that is gray-brown in color and forms in humid forests but under a variety of conditions. It is rich in clay and plant nutrients. *Alf* refers to aluminum (Al) and iron (Fe), making it essentially equivalent to a pedalfer, indicating that they are found all over the eastern United States, among other places.

*Andisol.* A soil type that forms in volcanic ash. These soils are composed of altered glass and unstable mineral fragments and, as such, undergo rapid changes in composition. They are very fertile, supporting a huge variety of crops, but they are regionally restricted. The Cascades, Aleutians, and Hawaiian Islands contain the best examples of this soil in the United States.

*Aridisol.* A soil that forms in the desert and is equivalent to a pedocal. It has low organic components and accumulates minerals that are normally removed by water.

*Entisol.* A very young soil that is lacking in structure and shows characteristics of the parent material. These soils form in areas that are very active or slowly weathered. They may form on active slopes or in rivers and are common in the Rocky Mountains and Basin and Range Provinces and in California. They tend to be very fertile, but because of physical instability or extreme conditions, they may, in many cases, not support significant vegetation.

*Gelisol.* A soil type that is young and forms in areas of permafrost. These soils are frozen a good part of the year, so soil profile development is slow and poor. They are typically just A horizon resting on permafrost. Although the organic layer may be quite fertile, the extreme weather conditions greatly limit the development of vegetation of any kind.

*Histosol.* A black, highly organic-rich soil commonly referred to as peat and muck. It is composed almost entirely of partially decomposed vegetation and is therefore only O horizon. There are no climate implications for histosols, although presently they are more common in swamps along the southern and eastern coasts and in bogs along the northern border (areas affected by glaciation) of the United States.

*Inceptisol.* A young soil in which a recognizable profile is at its initial stages of development. It tends to form relatively quickly through alteration of rock and sediment in humid climates. It is most common in the forested northwestern and glacially scraped northeastern parts of the United States.

*Mollisol.* A soft, dark-colored soil that most commonly develops from long-term growth of grass. It is a highly fertile, organic-rich soil with good A horizon development and high calcium and magnesium contents. Mollisols are also among the newer types of soils because extensive grassy areas only developed in the Eocene. They are characteristic of prairies and, as such, underlie the entire Great Plains of the United States. They can occasionally form in forested areas, where there is extensive earthworm activity, but this is rare.

*Oxisol.* A highly leached soil that forms in tropical climates and is equivalent to a laterite of the old system. This soil type tends to be infertile because of the extensive leaching and is very rich in aluminum with lesser amounts of iron, all in oxide form, thus the name. The vast vegetation that grows on this soil type in rain forests actually grows in the leaf litter above it. Although the soils of the deep southeastern United States approach oxisols, the only true modern oxisols may occur in some of the tropical islands of the U.S. possessions. They are much more common in Central and South America.

*Spondosol.* A soil that occurs only in humid regions on a sandy substrate. The A horizon is composed of weathered organic material, but the B horizon contains light-colored leached material, which is the distinctive feature of this soil type. These soil types are common in cool, humid pine forests of the northern United States and some minor areas at higher elevation.

*Ultisol.* A highly leached red to yellow soil that forms through long periods of weathering. It is characterized by low fertility and is highly acidic, rich in aluminum and iron, and poor in calcium. The *ulti* part of the word is from *ultimate* because it is the ultimate product of weathering. These soils are common in the southern and southeastern United States.

*Vertisol.* A soil that is characterized by a high content of expanding clays. This soil is common in

arid areas with wet and dry seasons, forming deep vertical cracks when dry and puddles when wet. It commonly forms through the weathering of basalt and can be found in Colorado and other areas of the western United States.

### POLLUTION OF SOIL

Soil is polluted on a daily basis at numerous levels of volume and impact. As a result of this pollution, there is an ongoing battle between polluters adding pollution and remediators removing it that determines the total amount of polluted soil. Although there has been pollution of the soil dating from the first settlement of humans, the industrial age turned this largely inconsequential and recoverable pollution into a major epidemic. The complete lack of regulations on industry for hundreds of years left a legacy of soil pollution in virtually all the old industrial centers. Many of the specific company sites in these areas are current Superfund sites. Now, as a result of efforts by the U.S. Environmental Protection Agency (EPA) and many state and federal agencies, the spread of soil pollution is somewhat controlled. Cleaning up the legacy of pollution, however, will take many decades and cost billions of dollars.

Pollution can enter the soil in a variety of ways. Most simply, it can be dumped directly on the soil surface in a dump or landfill. Entire communities have dumped their refuse in large pits to dispose of it. Not only has the refuse polluted the soil directly, but polluted fluids, called leachate, have then been emitted from the landfill or have been produced by passing rainwater and other precipitation. This leachate has further polluted deeper levels of the soil beneath and around the landfill by infiltrating it and depositing pollutants. This practice largely ended in 1976, when the U.S. Congress passed the Resource Conservation and Recovery Act (RCRA), which required that all dumps be converted to sanitary landfills. After this, landfills had to be engineered and constructed to prevent leakage and restrict pollution.

Landfills and dumps produce point source pollution, because the source can be uniquely identified. Other point source pollutants include spills and leaks from manufacturing, transportation, and storage facilities, as well as disposal wells, septic systems, industrial lagoons, underground storage tanks, and many sources in residential dwellings. There are also many nonpoint source pollutants that do not have identifiable sources. These include pesticides that are sprayed onto the soil surface or mixed into the soil, air pollution deposition onto the soil by gravity fall-

out or precipitation washout, fertilizers, road salt, and other road grime, among other sources. All of these processes spread pollution into soil.

Once the pollution is in the soil, it may be fixed and immobile or mobile and able to leach into the groundwater. The mobility of a pollutant depends on its chemistry. Generally, water-soluble pollutants are mobile because they can be dissolved in infiltrating water from precipitation and carried away. This process cleans the soil but affects the groundwater. Most heavy metals and other chemically stable solids do not dissolve or chemically react to form compounds that may be flushed out. They essentially form sediment in the soil and remain fixed. Many organic pollutants adhere to clay and organic particles in the soil by chemical processes and remain fixed. Some of these and the mobile organic compounds are broken down to less harmful compounds through the action of microorganisms, which use the pollutant as a source of food and clean up the pollutant in a natural form of bioremediation. This and other natural pollutant removing processes are known as natural attenuation. The most difficult problem arises with some of the pesticides, because they kill the microorganisms. In this case, they can be very persistent, remaining active in soil for decades. This is the case with dichlorodiphenyl trichloroethane (DDT), but there are several other pesticides in the same category.

**soil pollution** The soil of the planet Earth has been a dumping ground for refuse since the beginning of time. Prior to the Industrial Revolution, this did not present much of a problem except for mining and smelting operations because most waste was biodegradable. Left alone, the impacted area would quickly return to its natural state. In the case of mining operations, the waste rocks that were removed from underground do not biodegrade, carry potentially dangerous compounds to the surface, and can take hundreds to thousands of years to break down. If they are smelted, the result is even worse. Smelting is the first step in chemical refining: It splits the chemicals in a mineral compound to yield a target element, usually a metal in ancient times, and waste elements. The waste elements could include sulfur and sulfur compounds that could cause local acid rain and acid mine drainage as well as unanticipated heavy metals such as mercury, lead, chromium, and cadmium. Any of these contaminants could cause severe environmental problems. Fortunately, mining and smelting operations were generally small for most of human history.

The Industrial Revolution changed this relatively sustainable human existence. The first major pol-

lutant was coal, which remains a problem today. In addition to all of the soot it produces and unwanted air pollutants it releases, the mining and storage of coal can produce significant pollution. If coal mining and usage had remained a small operation, the environment could have absorbed much of the pollution. It did not. Coal mining and usage supplied the power for the Industrial Revolution and spread everywhere by trains. Between the dust and the contained impurities such as sulfur, mercury, and other heavy metals, coal caused significant widespread soil pollution by emissions and dumping of waste. The practice of simply dumping waste and producing emissions no matter how dangerous and unsightly became the norm for the Industrial Revolution. As more dangerous compounds were developed, the practice did not change, and pollution intensified and increased. It was not until the advent of the environmental movement in the 1960s and 1970s that the practices would change and even then, only because they became illegal and had a steep cost attached to them. It would be even longer before a significant proportion of the population became concerned about damage to the environment.

Installation of a residential-type septic tank (AP Images)

There are several problems associated with contaminants in soil. If they are soluble contaminants, infiltrating water can leach them into the groundwater system and contaminate drinking water supplies. Some can be taken up by plants and incorporated into the leaves, stems, and fruit. If they are immobile, erosion can remove the soil and transport them as particles into surface water and contaminate it and the sediments deposited at the bottom. Some contaminants can evaporate from the surface of the soil, or the soil can dry out and be carried away by the wind as particulate, both processes contributing to air pollution. In these ways, soil pollution can contribute to pollution of all other media.

### HEAVY METALS IN SOIL

Heavy metal pollutants include the metallic elements that are considered to be potentially dangerous. Originally, the term applied to metals with density greater than 6.0 g/mL, but this reference is not strict any more. Heavy metals are emitted to the soil by mine waste, settle out (fall out) or are washed out (by precipitation) from air pollution, and from direct dumping. These heavy metals—including arsenic, cadmium, chromium, lead, mercury, and zinc, among others—can be emitted in various compounds with a number of valence states. These conditions determine how immediately toxic each will be. For example, dimethyl mercury is highly toxic in very small quantities, whereas in nonmethylated states, it is far less dangerous. Hexavalent chromium is more dangerous than trivalent. The concentration of the heavy metal is also important. Many of these metals occur naturally in rock and soil in very small quantities and are relatively unimportant pollutants. If concentrated by natural or anthropogenic processes, they become far more hazardous.

As far as high concentrated levels of pollutant, mine wastes are certainly among the worst. Minerals with high amounts of heavy metals are commonly relatively unstable at the Earth's surface. The deep weathering of rock surfaces that occurs over the thousands to millions of years that develop most landscapes generally breaks down such minerals. Through hydration and oxidation reactions, they are removed to clays and other minerals and dispersed. When mining takes place, fresh unweathered and highly reactive minerals are taken to the surface and exposed to the elements. In addition, the rocks are crushed into small pieces. The smaller the fragment, the more surface area it will have. Mine tailings, therefore, have highly unstable minerals with high surface area upon which chemi-

cal reactions may take place. These chemical reactions release the heavy metals that are concentrated in most metallic deposits from the minerals and into the environment. The initial weathered material from mine tailings is highly enriched in heavy metals and can cause environmental health issues in the area. With time, these emissions will lessen, but they will remain well above background levels for centuries. For these reasons, mine soils can be great sources of pollution.

Direct dumping of waste from industrial sources also contributes toxic doses of heavy metals to the environment. Commonly, the metals in industrial waste are in their most hazardous state. For many decades, industry simply dumped waste solids and wastewater on the ground outside the manufacturing facility. The concentrations of these metals are as high as or even higher than would be found in a natural deposit of them. Berry's Creek, New Jersey, for example, has a Superfund site where there are layers of liquid mercury in the soil strata. It is the most polluted mercury site in the world. There are examples of such dumps for every heavy metal.

Heavy metals may also contaminate soil by air pollution fallout or precipitation washout. This process can occur in a number of places. Manufacturing facilities can release metals into the air as dust or vapors, especially in metal processing facilities. Incinerators have historically released metals in the fly ash from smokestack emissions. Coal-burning plants may release mercury and other metals along with sulfur compounds that can be carried by the air and deposited on the soil. The concentrations of the contaminants are highest in soil closest to the source and gradually decrease away from it. Concentration is typically highest in the direction of the prevailing winds. With recent stringent regulations on smokestack emissions of many pollutants including mercury, for example, requiring scrubbers and other emission reduction devices, there are fewer contaminants being deposited today. The legacy of old pollution, however, can be quite intensive.

Unlike many other damaging soil contaminants, such as phosphorus and sulfur, heavy metals are typically tightly fixed in the soil and remain for a long period. Unlike organic pollutants, they cannot be converted into other, less dangerous chemicals other than by changing valence states. Almost all cannot be leached into the groundwater system to any appreciable amount, as sulfur, phosphorus, and many organic contaminants can. Some can undergo limited bioconversion from one valence state to another. Some plants such as tobacco can take up certain metals into the plant structure. Otherwise,

## GOLF COURSES AND POLLUTION

There are few sports that are as intimately tied to the land and its topography as golf. Although the game's origins are unclear, with France, China, and the Netherlands laying claim to having developed a form of play as early as the 13th century, it is Scotland that is most often mentioned as the place where the modern game of golf, or *kolf* (Dutch for "club") first became recognizable. Thought to have been devised by bored shepherds competing to hit rocks as far as they could with their staffs, the links were rabbit holes connected by paths in the grass trodden down and widened by predators, sheep, and people. Fairways, a Scottish nautical term for the easiest sailing route between two ports, took advantage of the local topography and geology. In the most famous golf course in Scotland and probably the world, St. Andrew's, water hazards are flooded glacial potholes, and sand traps are places where glacial outwash had deposited reworked fine silt and sand. Despite this intimate connection with the land, however, golf is not a particularly environmentally friendly game.

There are about 15,000 highly manicured golf courses in the United States today. Unless they are properly designed and managed, courses can require extensive amounts of energy, agricultural chemicals, and water to maintain their functionality. Although the clubhouse may be the social focal point of a golf course, the maintenance department is its true center. It is at the maintenance shed or building where equipment for irrigation and mowing and spare parts are kept and stored, along with fuel, cleaning solvents, fertilizers, and pesticides. The two maintenance activities that can have the most impact on the groundwater underlying a golf course are fertilizing and pest management.

Golf courses are covered with turfgrass, a type of lawn cover produced in an intensively managed agricultural operation (i.e., sod farm), removed intact with a minimal amount of soil, and transplanted to another location. Mature turfgrass sod is carefully and professionally cultivated, cut into squares or rolls with the underlying soil and roots, and shipped to a nursery or job site to be replanted. Turfgrass can also be established and maintained by vegetative propagation using pregrown plugs or by direct seeding. Common turfgrass species grown in the United States include Bermuda grass, centipede grass, fine fescue, Kentucky bluegrass, ryegrass, St. Augustine grass, tall fescue, and zoysia grass. Each grass has advantages and disadvantages: Some like shade, some require lots of water, and some are wear-resistant, and golf courses

often use a number of species to maintain various parts of their fairways, greens, collars, and so forth. Turfgrass selection, cultivation, and maintenance are the most highly scientific and technically demanding parts of maintaining a playable golf course.

Usually, turfgrass sod cultivation is a local business within 150 miles (241.4 km) or so, as climatic conditions must be similar in the growing and planting areas. Turfgrass sod is classified in two general categories, cool-season grasses such as bluegrass and tall fescue and warm-season grasses including Bermuda grass and zoysia grass. Cool-season grasses grow best in the northern parts of the United States, as well as in areas with higher elevations and coastal regions where evening summer temperatures are in the 50–60°F (10–16°C) range. Warm-season grasses are usually grown for use in southern Florida, along the Gulf Coast, and throughout the Upper South.

Once a golf course has selected a turfgrass or, more likely, the several species of turfgrass that it will be using, the expensive plantings must be maintained and cultivated. Maintenance is done through the use of fertilizers and pesticides. Fertilizers are needed to ensure that turfgrasses remain healthy under the heavy use they receive during playing times and seasons on the course. The primary fertilizers needed by turfgrasses are similar to those of most plants, nitrogen (N), phosphorus (P), and potassium (K). These three elements are essential plant nutrients, and growth is not possible unless sufficient quantities are available. Nitrogen is an essential component of all proteins, and, as a part of the deoxyribonucleic acid (DNA) molecule, it is essential for both growth and reproduction. Plant stunting is a common symptom of nitrogen deficiency. Phosphorus is needed by plants for the conversion of light energy to chemical energy, adenosine diphosphate (ADP) to adenosine triphosphate (ATP), during photosynthesis. It is essential for plant growth and flower/seed formation. Potassium regulates the opening and closing of plant stomata, the pores on the underside of the leaf used for gas exchange and in moisture regulation. Without sufficient potassium, the plant is unable to regulate the amount of water it takes in or loses. Potassium deficiency may cause necrosis (cell death) or interveinal chlorosis (loss of color).

Nitrogen as N is not bioavailable and must be supplied to plants and animals in another form, as either nitrate (NO<sub>3</sub>) or ammonia (NH<sub>4</sub>). The same holds true for phosphorus, which is usually chemically combined with oxygen to form phosphate (P<sub>2</sub>O<sub>5</sub>), and potassium,

in the form of KCl or potassium chloride. Fertilizers are the commercial end products of these chemical combinations and are expensive to purchase and expensive to apply, requiring the use of specialized equipment and trained personnel. A major objective of a well-founded fertilizer management program is to supply these essential plant nutrients at the proper time and in the proper amount to support plant growth and development, with no excess. Excessive quantities of nitrogen and phosphorus only result in excessive weed growth and possibly turf disease, rusts, and burns, but also can contaminate groundwater and surface water.

Excess fertilizers are removed from golf courses in two ways: in surface water or in groundwater. Fertilizer that is not taken up by plants can be washed by rainfall into the local drainage system and eventually into the regional watershed. Nitrogen poses particular problems as a component of fertilizer because it can cause surface water eutrophication. This condition occurs if lakes, estuaries, or slow-moving streams receive excess nitrogen and phosphorus. As they do on land, these nutrients stimulate excessive aquatic plant growth (algae and periphyton). This enhanced plant growth, often called an algal bloom, leads to reduced dissolved oxygen levels in the water when bacteria consume the dead plant material. It can lower dissolved oxygen levels needed by more developed organisms, such as fish. Algal blooms also decrease the amount of sunlight penetrating the water and reduce viable habitat for many near-surface plant and animal species.

Nitrogen and phosphorus can originate not only from golf course runoff, but also from many other sources such as agricultural fields, suburban lawns, and sewage treatment plant discharges. Water with a low concentration of dissolved oxygen is called hypoxic (low oxygen) and has a dissolved oxygen concentration of less than 2 ppm. Water fully saturated with oxygen has a dissolved oxygen concentration of 12 ppm.

If excess nitrogen enters the groundwater via leaching, it can have a disastrous consequence on public health. The maximal level for nitrogen in water is set at 10 mg/L by the U.S. Environmental Protection Agency. This regulatory limit was developed in order to protect babies and infants whose immature digestive systems contain a type of bacteria that change nitrate ( $\text{NO}_3$ ) into nitrite ( $\text{NO}_2$ ). The nitrite reacts with hemoglobin, which carries oxygen to all parts of the body, to form methemoglobin, which does not carry oxygen. As the level of methemoglobin increases, depending on the amount of nitrate

ingested and converted, the amount of oxygen being carried throughout the body decreases. Eventually, blood oxygen levels fall to below life-sustaining concentrations, and the baby suffocates. This condition is called methemoglobinemia, or blue baby syndrome, because the most obvious symptom of nitrate poisoning is that the skin turns a bluish color, particularly around the eyes and mouth. The blood sample of an affected baby is chocolate brown instead of a healthy red. Nitrate poisoning can be treated, and in most cases the baby makes a full recovery. Around the age of three months, an increase in the amount of hydrochloric acid in a baby's stomach kills most of the bacteria that convert nitrate to nitrite. By the time the child is six months old, its digestive system is fully developed and none of the nitrate-converting bacteria remain.

Pest management is another way that golf courses can adversely affect local water quality. To protect their turfgrass investment and to maintain playable fairways and greens, most golf courses use agricultural chemicals in the form of pesticides to help control weeds and vectors. If properly stored, mixed, and applied, turfgrass pesticides, when used in combination with other insect management techniques—biological controls, such as establishment of habitat for insect predators; and mechanical controls, such as traps and buffer zones, among others—can have a minimal impact on surface water and groundwater quality. Overuse of pesticides, however, or their improper application or storage, has resulted in the contamination of groundwater underlying golf courses.

There are three types of commonly used pesticides on golf courses: Fungicides such as iprodione, chlorothalonil, and anilazine to kill fungi; herbicides such as bensulide 2, 4-D acid (Trimec) and mecoprop sprayed on turfgrass to control weeds; and insecticides, which include carbaryl, chlorpyrifos, and bendiocarb. Many of these and other pesticides are known or suspected human carcinogens, and exposure to them can have serious health consequences. Fortunately, many characteristics of pesticides that make them useful turfgrass management tools also make them fairly immobile. These properties include a tendency to "stick" to plants and insolubility in water, among others. Studies by both the U.S. Geological Survey and U.S. Golf Association have found that groundwater quality underlying most golf courses has been only minimally affected by pesticide applications. Even the widespread use of pesticides at 52 golf courses on

*(continues)*

(continued)

Long Island, New York, at very high levels, 18 pounds (8.16 kg) per treated acre, has not resulted in widespread contamination of underlying groundwater supplies. Currently, golf course operators and groundskeepers on Long Island and across the United States are well aware of the possible environmental damage that can be caused by the improper use of these dangerous chemicals and have implemented programs to limit their application and improve their effectiveness.

Other types of environmental impacts from golf courses are those that commonly are associated with related commercial activities. These include releases of petroleum products from underground tanks used to store maintenance vehicle fuels; improper disposal of used oil, antifreeze, and lead acid batteries from golf carts; and discharge of untreated wash water and equipment rinsate containing oil, grease, fertilizer, and pesticide residues. Most golf courses have established special storage and washing areas that are designed to isolate and contain these types of materials from the environment. Equipment washing and container rinsing, for example, are done on a concrete pad where wastewater is diverted to a sump and then pumped into a holding tank for later pickup and disposal. Underground storage tanks at golf courses are subject to the same regulations and upgrades for spill containment and leak detection as those at any gas station.

Many golf courses have developed integrated pest and fertilizer management plans, procedures that utilize a variety of techniques that help minimize agricultural chemical applications. These include setting threshold levels to identify when and where pest populations or turfgrass condition require action. In other words, the presence of a single bad bug or brown patch of grass may not require the application of pesticides and fertilizers across the entire course. Regular monitoring of course agriculture also is done so that chemical applications can be tailored to turfgrass conditions, rather than being performed on a routine basis. Different horticultural methods also

are used, such as selecting pest-resistant varieties of turfgrass and planting pest-free rootstock. These methods can be effective and cost-efficient while not presenting a risk to people or the environment. Finally, when an application of agricultural chemicals becomes necessary, substances that present the least public health and environmental risk can be chosen. Examples include highly targeted chemicals, such as pheromones to disrupt pest mating, or mechanical control, such as trapping or weeding. If further monitoring indicates that these less risky controls are not working, then targeted spraying of pesticides can be followed by broadcast spraying of nonspecific pesticides as a last resort.

by Robert P. Blauvelt

they basically remain where they are deposited until they are physically moved or diluted with clean soil.

### ORGANIC POLLUTANTS

Organic contaminants are introduced into soil by leaks in manufacturing, transportation, and storage; air pollution fallout and washout; spraying; and direct dumping. They are universally less persistent than the heavy metals and degrade in as little as a

few hours to as much as several decades, in most cases. Many are susceptible to biodegradation and alteration, and they contain carbon compounds that can be used for energy. Organic pollutants are far more abundant than inorganic pollutants. In short, virtually every person has contact with some organic pollutant every day of his or her life.

The organic compounds that are purposefully sprayed or applied to soil are mainly used for agricultural and landscaping purposes. These pollut-

ants are pesticides, herbicides, and fertilizers and are probably the most damaging of all pollutants to the environment. Most are very soluble and can be readily leached into the groundwater system and are found in drinking water supplies throughout the country. Some may be adsorbed to clay or organic particles and remain fixed. These are the most persistent of the organic compounds. Some pesticides are so potent that they are even toxic to the microorganisms in the soil and must be broken down by chemical reactions. They add even more persistence. Some pesticides are designed to be systemic and are absorbed into the root system and distributed throughout the plant. Fertilizers and pesticides can be washed from the soil in surface runoff and transported to surface water systems. They can have devastating effects on these systems as well.

There are huge amounts of organic pollutants in the air from numerous point and nonpoint sources. Probably the most abundant is from automobile exhaust, evaporation of volatile organic compounds, and other burning. Most of these organic pollutants remain in the air until they are degraded. Some, however, are washed out in precipitation and enter the soil system. Soot settles to the ground by gravity and can cause problems if there is enough, but most is readily absorbed into the soil system and degraded by microorganisms.

Leaks of organic compounds into the soil are very common. The majority of these leaks are from underground storage tanks (USTs). The most frequent of these leaks are at gasoline stations and home heating oil tanks. The contamination from them largely affects groundwater, but the pollutant must pass through soil to reach the water table. The plume really rides on top of the water table and infiltrates soil through the entire migration. As it does, it leaves behind petroleum, coating the particles and filling small pores. In this way, the soil is also contaminated. The same leaks can occur in pipelines and manufacturing facilities.

Direct and deliberate dumping of organic pollutants produces a very dangerous site. Some of the most troublesome Superfund sites involve industrial organic pollutants. An example is the 200-mile (320-km) stretch of the Hudson River in New York State. General Electric dumped huge amounts of polychlorinated biphenyls (PCBs) into the river during the middle part of the 20th century. Although it primarily affects river sediments, it also affects soils along the river. Two of the largest cases of organic soil pollution and two of the most important polluted sites in the world are Love Canal, New York, and Times Beach, Missouri. There are

many others in which the pollution of soil is the most important impact.

Soil pollution is a grave danger to the very survival of the human race. Soil produces the vast majority of the food we consume whether directly or indirectly as feed for livestock. As humans attempt to squeeze every drop of productivity out of agricultural lands, there are risks of catastrophic collapse. There have been examples in the past of soil mismanagement that threatened to restrict productivity such as the dust bowl of the American Midwest as well as numerous cases of desertification around the world. There have been numerous individual cases of soil pollution that rendered large areas ecologically dead, primarily from mining and smelting operations. The areas around Norilsk, Russia; Sudbury, Canada; Ducktown, Tennessee; and Palmertown, Pennsylvania, are just four examples of such disasters, and there are many more. Fortunately, society has realized the danger of these situations and taken deliberate actions to prevent them from continuing and to remediate the problems. It is a credit to the human race that they have understood the value of productive soil in these cases and have taken steps to address many of the other problems as well.

### **Southern Crop Services Delray Beach, Florida (1988–2008) Soil and Water Pollution**

There are few movie scenes more memorable than the classic 1959 Alfred Hitchcock thriller *North by Northwest*, when Cary Grant was chased into a dried cornfield and covered with pesticides by a buzzing World War I vintage biplane. Crop dusting, also known as aerial application, is the method by which fungicides, pesticides, and herbicides are dispersed onto crops or cropland from an airplane or helicopter. Fertilizing, or top-dressing, and seeding also have been done from airplanes, especially in areas where more traditional methods are difficult, such as hillsides and marshy soil. One of the first documented uses of aerial seeding was in 1906, when a tethered balloon was used to spread seeds over a swampy patch of ground in New Zealand.

It was in 1921, when a surplus Curtiss JN-6H biplane, the Jenny, with a metal drum strapped to its undercarriage and piloted by a U.S. Army Air Service officer, that crop dusting began in earnest. Flying just above a fruit orchard that was being devoured by *Catalpa sphinx* moths near Troy, Ohio, Lieutenant John MacReady pulled a lever mounted just outside the cockpit and discharged a load of powerful lead arsenate insecticide that ended the infestation within a few hours. This act founded the new industry of crop dusting, which would play a pivotal role in American agriculture. The Delta Dusters Company started out providing aerial application services and evolved into a major airline.

Aerial application expanded greatly after World War II, with a large number of pilots and surplus planes available. This expansion was aided by the interest of the American farmer in applying organophosphate and organochlorine pesticides. Crop dusting planes became more sophisticated, and eventually the Piper Pawnee, a specially designed low-wing monoplane with a high cockpit for increased visibility and anticorrosion features in its fuselage to protect against chemical damage, emerged as the plane of choice for aerial application. Other models with similar features such as Cessna's Ag-Wagon and Grumman's Ag-Cat also were widely used.

### **POLLUTION OF THE SITE**

Riding this wave of pesticide use was a company called Southern Crop Services, or SCS. Founded in the late 1940s in Delray Beach, Florida, about 20 miles (32 km) south of Palm Beach, SCS operated as an aerial application service until 1992, with a name

change in the mid-1980s to King Aerial Service. Not much to look at, the 30-acre (12.1-ha), grass-covered property occupied by SCS included a runway with a few small trailers at one end and a drainage ditch along its eastern boundary. Major parts of SCS's operations were the mixing and storage of the pesticides that were loaded onto the wing and belly tanks of its planes, and it was these activities that eventually converted this nondescript airfield into one of eastern Florida's most notable hazardous waste sites.

When pesticides are shipped from the manufacturer to the customer, they are often transported as a concentrated solution or a dry powder. Prior to application, they are diluted and/or mixed with a solvent. Typical solvents are water, kerosene, or some fluid that evaporates readily or even a separate agent or compound to increase its effectiveness. Today, pesticide mixing is done on well-ventilated, concrete pads that are surrounded by curbs or have other types of secondary containment that reduce the chance that spills will enter the soil or groundwater system. In the 1940s and 1950s, however, such protection was not common, and pesticide mixing and storage areas on farms, ranches, and airports were common sources of soil and groundwater contamination.

In addition, when airplanes returned from an aerial application, their pesticide storage tanks were cleaned or rinsed before being reloaded, especially if a different product was going to be used. These pesticide-rich wash waters were discharged onto the soil or into a drainage ditch or pond and allowed to seep into the ground, causing local and sometimes widespread environmental effects. Occasionally, aircraft returned with surplus pesticide in their tanks that was emptied or purged with compressed air or high-pressure water onto an unpaved area or ditch near the runway. This waste contaminated both the soil and the groundwater.

These types of practices at SCS and other aerial application companies across the United States were commonplace and resulted in on-site contamination, primarily by the discharge of pesticide rinsates from mixing vats and aircraft spraying systems into a shallow on-site disposal lagoon or directly onto the ground. SCS also buried drums and other types of containers that had contained pesticides, and leakage from pesticide drums into the soil and groundwater system further contributed to the contamination.

By 1977, the 8,400-cubic-foot (238-m<sup>3</sup>) unlined lagoon that SCS had been using for pesticide tank rinsates and discarded chemicals was full, and there were reports of its overflowing and washing onto an adjacent property. In August 1983, the Palm Beach County Health Department directed SCS to stop using the lagoon and to conduct a contamination

assessment of its property. The study was completed in early 1984. It revealed that pesticides including toxaphene, dichlorodiphenyltrichloroethane (DDT), DDD, and parathion and heavy metals including arsenic, zinc, and copper were detected in soil and shallow groundwater in the area near the lagoon. SCS made an early attempt at cleanup, excavating sludge in the lagoon and stockpiling it on-site for later disposal, but the magnitude of the problem quickly overwhelmed the resources of this small company.

### THE CLEANUP

Using a risk-based approach, the Florida Department of Environmental Regulation (FDER) established a surface soil (upper 24 inches [61 cm]) cleanup criterion for SCS of 50 parts per million (ppm) of toxaphene. This meant that soil at the surface containing this concentration of toxaphene or less could remain on-site and not cause an unacceptable public health risk. The 50-ppm concentration also did not pose a threat of groundwater contamination. FDER later established a risk-based level of 100 ppm toxaphene for subsurface soil (deeper than 24 inches [61 cm]). On the basis of previous site studies, it was determined that at least 3,000 cubic yards (2,294 m<sup>3</sup>) of soil was present at the site that contained 50 ppm or more of toxaphene. Chlorine- and phosphorus-based pesticides were found at similarly high levels. Toxaphene also was detected in a groundwater sample from an on-site supply well.

The U.S. Environmental Protection Agency (EPA) and FDER became impatient with the slow pace of SCS's remedial response, so in 1988 and again in 1990, they initiated their own program of soil/sludge and lagoon water disposal. In 1988, acting at the request of FDER, EPA excavated approximately 4,800 tons (4,355 metric tons) of soil and sediment that exceeded the toxaphene cleanup standard. These materials were treated on-site by a high-temperature thermal desorption incinerator. Clean ("roasted") soil then was redeposited at the site. EPA also treated more than 300,000 gallons (1.1 million L) of contaminated lagoon water. Treated water was discharged into a local drainage channel.

With regulatory pressure mounting for more aggressive remedial actions, SCS accepted the inevitable and signed a consent order with FDER to sell the property. The proceeds were to be used for both cleanup and reimbursement of FDER for its investigation and enforcement actions. The process took almost 10 years, but the site was subdivided and sold in 1996 to two real estate development firms.

A second removal action took place in May 1990; it resulted in the excavation and off-site disposal of

approximately 540 tons (490 metric tons) of contaminated sediment from the on-site lagoon. Another 250,000 gallons (946,353 L) of lagoon water was treated by carbon absorption to below detection limits (less than one part per billion [ppb] DDT) and then discharged to a nearby drainage channel.

Although the FDER and EPA interim remedial actions addressed the most seriously contaminated parts of the site, residual amounts of soil are still present, both on- and off-site, that are greater than state cleanup levels for unrestricted use. In addition, groundwater monitoring has indicated that low levels of arsenic and pesticides in the shallow water-bearing zone remain present in isolated areas on the SCS property. Fortunately, water supply wells in a residential area east of the site have not been affected. The problem was that the clean private wells precluded the SCS site from inclusion on the National Priorities List as a Superfund site and, therefore, federal money was not available to fund the rest of the cleanup.

By 2007, an estimated 35,000 tons (31,752 metric tons) of contaminated soil still needed to be removed, including off-site contaminated soil. This removal was to be completed by 2008, but implementation was complicated by the presence of nearby wetlands, which had to be protected during excavation activities. Once affected soil has been removed, FDER anticipates further reductions to approved cleanup levels in the arsenic and pesticide concentrations that have been found in the shallow water-bearing zone. Groundwater monitoring will continue after soil remediation to verify that this is occurring.

### space shuttle launches and air pollution

The *Saturn V* rocket, the largest ever built and operated by the National Aeronautics and Space Administration (NASA), successfully launched the Apollo Moon missions and the Skylab Space Station, and it continues to lift the space shuttle into orbit around the Earth. When the fuel in the *Saturn V* is ignited, it forces a massive, continuous thrust of hot gases downward through its vents and portals. This downward force results in an equal and opposite push of the rocket upward. Current space vehicles operate on a linear, multistage design. A single-stage-to-orbit (or SSTO) vehicle that can achieve orbit without discarding fuel tanks or motors is being evaluated by NASA. SSTO vehicles, which also would be reusable,

may be less expensive to launch and operate, although more expensive to design and build.

### TYPES OF ROCKET FUEL

The rockets and their fuels are stacked on top of each other, with the first stage the largest and having the heaviest fuel. When the first-stage rocket's fuel is exhausted, it is detached with a small explosive charge from the space vehicle and the second-stage rocket is fired. After the second-stage rocket's fuel is gone, the third stage is fired, and so on. By jettisoning the empty fuel tanks and associated rocket motors, the now-much-lighter spacecraft requires less fuel to reach its mission or orbital velocity and altitude. In addition, fuel selection can be optimized for its operational atmosphere.

The power, efficiency, and environmental impact associated with the use of rocket fuel are dependent

upon its chemical composition. NASA, the military, and commercial launch organizations generally rely on four types of propellants:

**Petroleum.** This type of rocket fuel is highly refined kerosene called RP-1 (refined petroleum). Rocket fuels need to provide their own oxidizer, and RP-1 is usually combined with liquid oxygen (LOx) and burned to create thrust at low altitudes. RP-1 is a fossil fuel, and its combustion products include carbon dioxide, sulfur and nitrogen oxides, and particulate matter.

**Cryogenics.** These types of propellants are a fuel mixture of liquid hydrogen (LH<sub>2</sub>) and liquid oxygen. Both components are liquid at only very low temperatures (hundreds of degrees below zero), but cooling and compressing them allows large amounts to be stored in appropriately sized containers. If they were left in their gaseous forms, huge fuel tanks would be needed to store sufficient amounts of hydrogen and oxygen to launch a spacecraft or missile. Cryogenic fuels are lighter and have about 40 percent more power by weight than petroleum or solid rocket fuels. The *Saturn V* second- and third-stage rockets are cryogenically fired and are used to insert the space shuttle into Earth orbit. The end product of this combustion process is water, making cryogenic fuel very environmentally friendly.

**Hypergolics.** Thrust from this type of propellant occurs as fuel of monomethyl hydrazine (MMH), or hydrazine, and oxidizer of nitrogen tetroxide (N<sub>2</sub>O<sub>4</sub>) ignite during mixing, requiring no ignition source. One of the major advantages of hypergolics is that they can be stored at ambient temperatures and pressures and the reaction can be started and stopped by simply shutting off the flow of either the oxidizer or the fuel. MMH and N<sub>2</sub>O<sub>4</sub>, however, are dangerously toxic and must be managed by highly controlled safety procedures. Hypergolics power the space shuttle's orbital maneuvering, attitude control, and reentry systems.

**Solids.** Also called solid rocket boosters (SRBs), these are the oldest rocket fuels, first developed in ancient China. Fuel and oxidizer are loaded into a steel shell and ignited to provide thrust. For the space shuttle, the oxidizer is ammonium perchlorate, and the fuel is a form of powdered aluminum. A third ingredient, polybutadiene acrylic acid acrylonitrile, binds the mixture. Initially a liquid, SRB is cured into a soft, rubberlike solid. Stable and easily stored, SRBs do not require complex propellant-feed systems and often are used to provide additional thrust during launch or during the final stages of a launch. The space shuttle uses the largest solid

rocket motors ever built with each reusable booster containing more than 1 million pounds (454,000 kg) of propellant, supplying almost 2.7 million pounds (1.2 million kg) of thrust. The majority of military rockets (intercontinental ballistic missiles [ICBMs], such as the Minuteman and Peacekeeper) also use solid rocket fuels.

## ENVIRONMENTAL EFFECTS OF ROCKET LAUNCHES

Space shuttle launches, as well as other types of space exploration or military rocket testing and development, produce adverse environmental effects. Most of the emissions that are seen during a space shuttle launch are water vapor or steam mixed with very minor amounts of combustion products. At 11 seconds before the main engines fire, a storage tower near the launch pad begins to discharge about 900,000 gallons (3.4 million L) of water from six large nozzles into a trench just beneath the launch pad. This water continues to flow for about 20 seconds after main engine ignition and acts as an acoustical barrier and flame deflector, protecting the shuttle from the noise and heat generated by the SRBs during a launch.

The exhaust gases from the SRBs, which provide about 70 percent of the launch thrust for the space shuttle, contain very small amounts of chlorine. This chlorine combines with water vapor to form hydrochloric acid mist, which has caused some damage to wetlands and plants near the launch pad. NASA tries to mitigate these effects by launching when local winds blow this mist out to sea, where it is quickly neutralized by seawater.

As the space shuttle climbs into orbit, exhaust gases released into the thermosphere, the outermost layer of the Earth's atmosphere, settle and condense into a cloudlike layer of ice crystals. This layer, which has been detected in the sky over the Arctic, results in a "night-shining," or noctilucent, cloud, one that is not visible until the Sun's rays reflect off it from below the horizon. Although this small amount of additional water vapor is not likely to have an impact on either Arctic or worldwide atmospheric conditions, its presence is illustrative of the need to be alert to the environmental consequences of rocket launches.

Of more immediate concern is perchlorate, one of the primary components of SRB fuel. Perchlorate has been detected in groundwater and soil samples from more than 40 states. If ingested, perchlorate interferes with iodine uptake in the fetus, young children, and adults. The U.S. Environmental Protection

Agency is currently considering adding perchlorate to the list of chemicals that must be tested for under the Safe Drinking Water Act. California, Arizona, Nevada, and other states that have hosted significant amounts of rocket tests and launches are especially concerned over the presence of this compound in their local environments and its potential impact on public health.

On a global scale, about 11,000 tons (10,000 metric tons) of rocket propellant is burned in the atmosphere annually from both civilian and military sources. The release of chlorine, free radicals, and aerosols as a result of these launches, particularly those using SRB and hypergolic fuels, may be contributing to destruction of the ozone layer. Although the amounts of potentially ozone-depleting substances released by this activity are relatively small on an international scale, approximately 130,000 tons (117,900 metric tons) of ozone-depleting products was manufactured worldwide in 2003. They are, therefore, not insignificant, and part is delivered directly to the stratosphere, where they do the most damage.

The technologies to launch rockets into space were developed at a time when political and military agendas were the driving forces. Technological dominance over the Soviet Union far outweighed the environmental consequences on the American agenda. Those attitudes have changed in recent years, and space exploration must become more environmentally responsible in line with public opinion. Environmental Impact Statements are required before a new or expanded launch program can be initiated, and these programs must include measures to reduce or minimize both ecological and atmospheric effects. Extensive research is being done to find a cheaper, safer, and less environmentally damaging replacement for hydrazine-driven thrusters. Ion engines and electric propulsion systems are the leading candidates, along with short-term fuel combination changes that provide some environmental benefit through the more efficient mixing and matching of propellant types.

**streams** Streams are bodies of surface water that flow in channels, thereby draining water from higher to lower elevations. They may contain water from surface runoff both directly from precipitation and from the melting of stored precipitation in snow and ice. They may also contain base flow from groundwater directly infiltrating into the stream from springs. The proportion of these two components, base flow and surface runoff, varies considerably, depending upon the stream, season, climate, and other factors. Streams originate at their headwaters, where small tributaries in the drainage basin coalesce to form a larger stream or river. Streams are ranked according to their position relative to the river, which is considered a first-order stream. Tributaries feeding directly into a river are second-order streams, which are, in turn, fed by third-order streams.

The drainage pattern of the rivers and tributaries commonly reflects the underlying rock and soil units. In map view, a dendritic drainage pattern looks like the branches on a tree and reflects horizontal strata. A trellis drainage pattern contains tributaries that are generally straight and parallel but periodically contain right-angle turns. This pattern indicates tilted strata. There are several other patterns, which are less common.

Streams reflect the relative ruggedness or "age" of the topography through which they flow. Immature, rugged topography produces fast-flowing "young" streams in steep valleys and canyons, whereas mature, flat topography produces slow-flowing "old" winding streams in wide flat floodplains. There are also "middle-aged" streams, which fall between the two. The age of the stream really has no relation to its condition. A single stream may have "young" characteristics in its headwaters, "middle-aged" features in the midsection, and "old" features near the mouth. There are two end member types of streams that are common and characteristic. Generally, young streams are braided streams and old streams are meanders.

### BRAIDED STREAMS

As is illustrated by the name, the channels in a braided stream form a braided, or anastomosing, pattern. The channels surround lozenge-shaped channel bars of sand and gravel. During the summer and times of low rainfall and runoff, the channel bars are land surrounded by the thin channels filled with relatively gently flowing water. Discharge is low, as are velocity and sediment load. The bars remain relatively fixed with only minor winnowing of sand from the upstream end of the bar and deposi-

tion on the downstream end. Vegetation may even occur on the channel bars during this period.

During spring thaw or heavy rains, these streams become raging torrents with high velocities, discharges, and sediment loads. The river levels rise to the point that all channel bars are submerged. All sizes of sediment are transported, and rapid downstream migration and reshaping of the channel bars take place. All vegetation and structures that colonize the channel bars during the low-flow times are washed away during these times.

Deep Creek estuary near Broome, Australia, is an example of how yellow sand, carried by winds from the mainland, and gray silt collect in the estuary, narrowing the river's path. (Bernhard Edmaier/Photo Researchers, Inc.)

## COLORADO RIVER

One of the most tightly managed and hotly debated watersheds in the United States is the Colorado River. Flowing through Wyoming, Colorado, Utah, Arizona, Nevada, California, New Mexico and northern Mexico, the Colorado River has provided its resources for almost 800 years. Early Native Americans developed a sophisticated canal system to distribute water. These canals were later cleared and used by the first European settlers in the 1860s. The

drainage basin of the river is 244,017 square miles (632,000 km<sup>2</sup>) but is not heavily populated, containing only three cities, Las Vegas, Phoenix, and Tucson, with populations greater than 50,000 residents. Considering the images of the wild river and the increasing number of people that it serves, it is surprising that the annual flow is only about 3 percent that of the Mississippi River and 10 percent that of the Columbia River. The arid climate and burgeoning population of the Colorado River watershed, however, make the water a more valuable resource than water in other areas, leading to many decades of conflict on a national to international basis and severe deterioration of water quantity and quality. Lacking a standardized set of pollution controls or water use criteria, each state and Mexico has sought to exploit the Colorado River for its own purposes, without regard to effects on downstream users.

**Map of the southwestern United States showing the Colorado River drainage basin**

### WATER USE CONFLICTS

Issues of water quantity are clearly the main concern in the Colorado River drainage basin. Several dams have been built along the river, including the famous Hoover Dam, to control water supplies. Water is piped out from these areas as far away as Los Angeles and the Imperial Valley of California. Usage is so heavy that in some years the river runs completely dry at its mouth and no water empties into the Gulf of California. This severely alters the ecology and sediment dynamics of the area. The level of conflict over water has escalated to near-wars, in some cases, and the potential for further conflict is very high. One of the fundamental bases for these conflicts is that water allocation rights were determined on absolute quantities (total gallons) that were measured during several uncharacteristically wet years, rather than

Braided streams occur in areas of rugged topography. They have steep valley walls, narrow floodplains, and generally straight courses. The volume of water varies greatly throughout the year, yielding a very large range for the river level. The valley walls are so steep, however, that lateral spreading of the stream during flood stage is minimal.

### MEANDERING STREAMS

Streams with highly sinuous channels that meander across the countryside as they make their way to the sea are called meanders. These channels are con-

stantly shifting across the wide floodplain that characterize meanders. The water in the stream flows straight so it strikes the bank on the outer arc of the curved channel, undercutting and eroding it. This is called the cut bank, and its erosion allows the channel to migrate slowly in the flow direction. On the opposite, inner arc bank, the stream experiences a much slower flow velocity. As the flow velocity drops, the stream can no longer carry sediments, and they deposit on the point bar that lines the inner arc. This process of erosion on one bank and deposition on the facing bank occurs continuously and accommodates the slow migration of the channel.

as a percentage or proportion of flow. Now, if a sustained dry period or prolonged drought occurs, flow rates along the entire river will decrease and there could be severe water shortages.

The plethora of court decisions, federal legislation, interstate agreements, and even an international treaty have come to be known as the law of the river. Two of the important early documents in Colorado River watershed management are contained in the Colorado River Compact of 1922, which divided users' withdrawal water rights between an upper basin and a lower basin. A treaty with Mexico in 1944 required the United States to deliver 325,829 gallons (1.85 km<sup>3</sup>) of water annually to Mexico. It took a U.S. Supreme Court decision in 1963 to settle a long-standing conflict over water appropriation between Arizona and California, the latter of which lost the decision and had to relinquish 130,332 gallons (0.74 km<sup>3</sup>). The Colorado Basin Salinity Control Act was approved by Congress in 1974. It was passed to prevent an increase in the salinity of river water because of overuse and prevented the construction of a desalination plant.

### POLLUTION OF THE RIVER

The Colorado River has pollution issues that are both common and uncommon. The common problems occur around the few cities along the river, where sewage overflow and other anthropogenic input degrade the quality of the water. The expanding recreation area around Lake Mead near Las Vegas, through sport activities on the lake and development along the shores, also degrades the quality of the water. The pollution problems that are uncommon include turbidity and salinity of the water. The lack of vegetation along the banks of the river and abundance of fine loose sediment within the watershed result in a heavy amount of fine particulate in the

river water. More may be added by direct erosion, surface runoff, or wind. This turbidity is especially an issue along stretches of the river where flow is rapid because it quickly deposits silt and fills in the area behind the dams. The arid conditions of the Colorado River basin produce very high evaporation rates. More evaporation causes an ever-increasing proportion of dissolved salt compounds. Although this is an issue all over the river, in flowing areas, the constant mixing reduces the impact of evaporation. Where the river is dammed, however, the length of time the water remains behind the dam, its residence time, is long, often measured in months or even years, and the amount of mixing that occurs between newly arrived water and water that has been present behind the dam for a long time is not significant. These factors lead to very high salinities in several areas along the river to the point where desalination procedures are necessary to make the water potable.

by Alexander E. Gates

Channels may also shift quickly in a process called avulsion. This can occur in one of two ways: neck cutoff or chute cutoff. When two channel loops in a meander belt slowly migrate toward each other, at some point they collide. At this point, instead of traveling around these large loops, the stream takes the shortest route to the ocean, abandoning the old channels. Water remains in these old channels, forming oxbow lakes along the sides of the active stream. Eventually, these lakes fill with sediment through weathering and erosion of the banks. Chute cutoff is also a channel abandoning process but occurs during floods. There is an overflow channel on the point

bar side of the meander loop. This overflow channel or chute makes a much shorter and straighter path than the main channel. During floods, the stream overflows the banks and floodwater flows through the chutes to help drain the extra water. If the flood is especially high, erosion of the shoot may be so deep that the entire stream shifts to the chute and abandons the main channel. An oxbow lake forms by this process, as well.

The topography is so flat around meander belts that flooding is common. When the stream overflows the river banks, velocity abruptly slows and sediments deposit on the bank edge. These deposits form narrow

mounds all along the stream course, called natural levees. They help to keep the stream in the channel and are commonly reinforced to reduce flooding. Flooding can be extremely destructive in meander belts because the large area of flat topography allows the stream to spread across a wide area. It is for this reason that these areas are extensively managed and become large-scale U.S. Army Corps of Engineer projects.

### POLLUTION OF STREAMS

Virtually all streams in the United States are polluted to some degree. Streams in industrial areas are highly affected and can be dead, supporting no aquatic life. Pollution can enter streams in a number of ways. Historically, streams and rivers made a convenient disposal site and pollutants were dumped directly into them. The practice was so brazen that discharge pipes from public sewer systems simply emptied raw sew-

age into rivers downstream of the city or town. The next city down drew their drinking water from the affected river, added their own waste, and, in turn, discharged it on the downstream side of the city, as well. It was estimated that by the time water reached the intakes for the city of New Orleans on the Mississippi River, it had been used six times.

Municipal wastewater discharge and the spills and leaks from industrial sites along a river form the majority of point source pollution into a river. Industrial plants have traditionally been located along rivers because of the ready source of water that might be used in manufacturing and processing and because of the convenience of the river for shipping products. Historically, the companies also discharged their waste directly into the water regardless of the environmental impact. In cases such as Ohio's Cuyahoga River, there were so many flammable chemicals in the water that the river periodically

Block diagram showing the morphology of streams and the possible sources of water that recharge the stream

**Maps of two general types of streams: Meandering streams occur in areas of flat topography, have slower flow velocity, and have sinuous channels with distinctive features (A); braided streams occur in areas of rugged topography, have high flow velocity, and have anastomosing channels with sediment stored in the channel bars (islands) between them (B).**

caught fire. In the Hudson River of New York, so much dioxin was dumped into the river that a 100-mile (160-km) stretch of it is a single Superfund site. Even if the waste was dumped or buried along the shore, flooding and runoff during precipitation and thawing events washed the pollution into the river. In the case of effluent streams, groundwater could also carry dissolved pollutants into the river through base flow. Clearly, industrial sites are capable of inflicting serious damage on the health of a river.

Surprisingly, nonpoint source pollution can be as dangerous as point source pollution. The mechanism for this pollution is the precipitation and subsequent surface runoff within the watershed of a river. The entire area from which water is derived to feed a river is its watershed. Depending upon the river, this can be quite a large area, up to thousands to hundreds of thousands of square miles. Anything that is applied to the surface generally enters the river eventually. In agricultural areas, runoff from fields can contain concentrated amounts of fertilizers and pesticides. In suburban areas, runoff flows from lawns, paved areas, and buildings into storm drains, which discharge directly into streams. The runoff can contain fertilizers, pesticides, road salt, motor oil and antifreeze, paint residues, detergents, solvents, and many other residential pollutants.

With all these dangerous pollutants in our rivers and streams, it might be surprising that the overabundance of fertilizer could actually be the greatest

threat. The active ingredients in fertilizers are nitrates and phosphates. They nourish plants and make them grow faster, larger, and stronger. In water, they nourish algae and other aquatic plants, which flourish even more than the land plants. When they die, microorganisms consume them and oxygen in the process. Hypoxic conditions result in the water, which can kill fish and other animals that depend on oxygen in the water. This process is called eutrophication, and nearly every body of water on land suffers from it. The more recent development is that the oceans suffer from fertilizers in rivers also. When the river empties into the ocean, it delivers water laden with fertilizers. Scientists used to believe that oceans were so large that they simply absorbed the nutrients. This belief was disproven when, in the 1960s, a large zone of eutrophication was found in the Black Sea in the USSR. Since then, such large dead zones have been appearing at the mouth of most major rivers worldwide. Today, there are some 200 dead zones, including one at the mouth of the Mississippi River in the Gulf of Mexico that is as large as the state of New Jersey. These dead zones make large areas of ocean completely unproductive and reduce the ability to produce sufficient food for the burgeoning human population.

### Stringfellow acid pits Glen Avon, California (1975–present) *Water Pollution*

From about the turn of the 20th century, the owners and operators of the Stringfellow Quarry Company blasted and removed granite from a 22-acre (8.9-ha) pit in the Jurupa Mountains, near the southern end of the Sierra Nevada in California. In 1956, they obtained a favorable land use variance from the Riverside County Planning Commission to operate one of California's few fully licensed class I Hazardous Waste Disposal facilities. They had made a fortune taking rock out of the ground; now, they would make an almost equal sum of money filling this hole in the earth with more than 34 million gallons (128.7 million L) of industrial waste, generated by metal finishing and electroplating plants from nearby Los Angeles, but also agricultural chemicals (primarily dichlorodiphenyltrichloroethane [DDT]) and organic solvents for the next 17 years, until 1973. Geologists of the state of California agreed with the description provided by the Stringfellow Quarry Company in its permit application that the granite taken from the mountain range left behind a natural impermeable bowl, one that would not leak. It was a perfect place to accept and process hazardous industrial waste, which would effectively isolate the material from the environment. Unfortunately, both the government geologists and the company were wrong.

### POLLUTION OF THE SITE

Just five miles (8 km) northwest of the city of Riverside and only one mile (1.6 km) north of Glen Avon, Stringfellow Quarry lies in a natural canyon on the southern slopes of the Jurupa Mountains. This canyon serves as part of the area's natural drain-

age network for Pyrite Creek, which feeds part of the Chino III groundwater basin. This basin stores and transmits potable groundwater for the 40,000 residents living in the relatively arid area of Southern California. Groundwater from this basin is also used extensively for industrial and agricultural purposes. Excess surface runoff from the canyon flows southwesterly through Glen Avon in a series of lined and unlined channels and ditches. Eventually, this water discharges to the Santa Ana River, approximately seven miles (11.3 km) from the site.

During site operations, disposal techniques included discharging liquid wastes, mainly acids and heavy metals, to ponds that were locally called acid pits and letting the water evaporate, as well as any liquid organic solvents or degreasers, leaving behind a sticky metal sludgelike residue. Once one pond was full, another was opened. Liquids also were sprayed high into the air to accelerate the evaporative process. The primary metals handled by the facility included chromium and cadmium in addition to other chemicals such as sulfuric acid and organic solvents including trichloroethene (TCE).

Site operations proceeded uneventfully until an unusually heavy rainstorm in 1969. Rainwater filled the open acid pits and flushed contaminated sludge and runoff down Pyrite Creek and through the center of Glen Avon. As a result, the community began to lobby for the closing and cleanup of the site. By 1972, under close regulatory scrutiny and with its customers starting to question the environmental integrity of the facility, the owners voluntarily ceased operations. The business unraveled quickly: The site's land use variance was revoked in 1974, and in 1975 the operating corporation notified the local Regional Water Quality Control Board (RWQCB) that it was financially unable to continue maintenance of the site. They had not paid any property taxes since 1973. The owners and operators of the Stringfellow Acid Pit site, as it was to become known, simply walked away.

### THE CLEANUP

In 1975, the RWQCB declared the nonoperating site a public nuisance and placed a lien on a plot of land filled with hazardous and toxic wastes. They later tried to sell this lien to raise money for the study and cleanup of the property. There were no takers. In 1978, the California state legislature appropriated funds for abatement activities at Stringfellow. Before these activities could begin, however, a heavy rainfall in spring 1978 again caused the waste pits on the site to overflow into Pyrite Creek. To prevent a catastrophic release, the RWQCB supervised the

release of approximately 800,000 gallons (3.03 million L) of chemically contaminated water into Pyrite Creek. The residents of Glen Avon were irate when these carcinogenic and toxic materials flowed past their homes and businesses.

Over the next three years, the RWQCB arranged for the removal and off-site disposal of approximately 6.5 million gallons (24.6 million L) of liquid wastes, as well as DDT-contaminated material. By this time, both the state and the RWQCB were beginning to realize that the magnitude of the environmental problems present at the Stringfellow site far exceeded their available resources. Fortunately, the national media had begun to focus the country's attention on sites such as Stringfellow, Valley of the Drums, Kentucky, and Love Canal, New York, and, on December 11, 1980, the U.S. Congress passed and President Jimmy Carter signed the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) into law. One of the most important parts of this groundbreaking legislation was the development of the National Priorities List, or NPL. This list served as a compendium of the United States' worst abandoned or inactive hazardous waste disposal sites, those that represented an imminent danger to public health or the environment. To provide money to clean up these sites, a tax was imposed on the petroleum and chemical industries, with those revenues going to a Superfund, a large pool of dollars created to fund the cleanup of those types of facilities.

The Stringfellow property was acquired jointly by the state of California and Riverside County via a tax deed, and, in 1981, California assumed sole title to expedite the cleanup. Although RWQCB pressed for complete removal of all wastes from the property, it became clear that the process would be prohibitively expensive. The state authorized funding to implement interim remedial measures of capping and pit stabilization to prevent further uncontrolled discharges from the facility and to study local groundwater to assess the extent of potential impacts from the site. Designated by the then-governor Jerry Brown as the most contaminated site in California, Stringfellow was added to the NPL in September 1983.

Another key component of CERCLA was the establishment of joint and several liability for those who caused or contributed to the contamination. Any business, company, or person whose activities resulted in the illegal disposal or release of hazardous substances or materials was responsible for the cleanup of the entire contamination, not just part of it. Using this new legislative authority, the EPA contacted the responsible parties (RPs), those com-

panies that were identified as having sent waste to the Stringfellow Acid Pit site for disposal. These companies became responsible for the \$150 million in remediation costs and subsequently reimbursed the EPA and state of California for most of the prior site stabilization and groundwater cleanup activities.

Over the years following the site's voluntary 1972 closure, a plume of contaminated groundwater had formed and extended more than one mile (1.6 km) from the Stringfellow site through Glen Avon. To address the groundwater contamination, the EPA constructed a slurry wall to block further contaminated groundwater migration and a French drain to capture contaminated surface water downgradient of the acid pits. In addition, a series of interceptor recovery wells were installed to remove contaminated groundwater and hydraulically to contain it from clean groundwater. These wells pumped the groundwater to a wastewater treatment plant. Once at the plant, the metals in the groundwater, including chromium, cadmium, copper, and zinc, were precipitated out by using lime. The water was then passed through a bed of granular activated carbon to remove the organic solvents (primarily TCE), and it was eventually discharged to the municipal sewer system for final treatment before release to the surface water.

Sludge from treatment operations was trucked 200 miles (320 km) to another California class I hazardous waste disposal facility. The treatment plant cost about \$10 million to build and about \$1.5 million per year to operate. It has been recovering and treating 200,000 gallons (757,000 L) of contaminated groundwater per week. It is still in operation.

### A FINAL PROBLEM

At the time, the Stringfellow site was one of the most notorious Superfund sites in the United States and, like any government program, was only as good as the people managing it. In this case, it was Rita M. Lavelle, a longtime California state Republican political figure. She was appointed as assistant administrator to USEPA in 1982 by President Ronald Reagan, also from California. Ms. Lavelle had worked developing environmental compliance policies for several major California-based corporations, and considering her political acumen and environmental advocacy, she seemed to be the perfect candidate for the job. Working closely with the EPA's national administrator, Anne Gorsuch (later Burford), Ms. Lavelle assumed responsibility for disbursement of Superfund monies. She and her staff determined the amount of money a particular site or community received for remedial activities.

The first signs of trouble appeared about 10 months after Lavelle's appointment. Her staff began grumbling that she was proindustry and that she was too willing to settle disputes quietly and allow companies to avoid more costly and reputation-damaging fines. In September 1983, a congressional subcommittee, which had been investigating EPA's handling of Superfund for several months, requested documents describing cleanup activities at 160 Superfund sites across the country. At about the same time, another subcommittee, acting on a complaint from EPA staffers and a community group near the Stringfellow site, began an investigation to determine whether Ms. Lavelle was preventing the release of a \$6.1 million remedial grant for Stringfellow until after the November election. The contention was that Ms. Lavelle did not want California's Democratic governor, Jerry Brown, to be able to claim credit for the cleanup of Stringfellow during his Senate campaign.

Both congressional subcommittees issued subpoenas for EPA documents, but Administrator Burford, acting at the direction of the White House, claimed executive privilege and refused to turn over any materials. Executive privilege commonly is defined as the right of the president and high-level executive branch officers to withhold information from those who have compulsory power, including Congress and the courts (and therefore, ultimately, the public), when there is a need to protect national security, the confidentiality of White House policy discussions, or legal deliberations. In testimony before one of the investigating House subcommittees, Ms. Lavelle denied that any such funding manipulation had taken place. She also denied that she ordered the EPA inspector general to harass an EPA staff member who had publicly criticized the agency on the popular news program *60 Minutes* for these and other types of politically based actions.

As Administrator Burford reviewed the EPA's internal documents, however, she realized Ms. Lavelle had attempted to manipulate Superfund disbursements for political reasons and had committed perjury. She met with Lavelle and requested that she resign. Lavelle refused, and President Reagan tersely fired her shortly thereafter. Ms. Lavelle was later convicted of lying to Congress and served three months of a six-month prison sentence. In 2004, Ms. Lavelle was found guilty once again for wire fraud and making false statements to the Federal Bureau of Investigation (FBI) in connection with a fraudulent billing scheme related to the disposal of hazardous wastes. She was sentenced to 15 months in federal prison.

Another Stringfellow casualty was Anne Burford, the former head of the EPA under President Reagan. After claiming executive privilege for the Stringfellow-related documents, as she was directed to do by the White House, Burford was indicted for contempt of Congress. As it became clear that the information in the documents was not related to policy development or national security, but rather demonstrated significant malfeasance by Ms. Lavelle, Burford urged President Reagan to release the documents. The information in the documents created political turmoil in the press and Congress, and there were several calls for Burford's resignation. Shortly after the release of the subpoenaed documents, the Justice Department advised Burford that they could not defend her in the contempt of Congress charge, and, facing a long and expensive legal battle, Anne Burford was forced to resign, along with 20 other senior EPA staff. In response, Congress rescinded the contempt citation. Ms. Burford died of cancer in 2004.

**Stumm, Werner (1924–1999)** *Swiss Aquatic Chemistry and Pollution* Dr. Werner Stumm is probably the single most important person responsible for the quality of water that is enjoyed in developed countries. Basically, he addressed and answered all of the first-order issues of water science, and all other researchers have been simply filling in the few holes that he did not address. His method was to explore the molecular aspects of the environmental chemistry of solid-fluid interfaces. This process revolutionized water science, and he literally wrote the book on aquatic chemistry with it. Although his

research was on the technical aspects of environmental issues, in terms of the understanding of chemical processes and interactions, it always had applied results, and he participated actively in the transfer of the theoretical to the applied processes. As a result, wastewater treatment plants run more efficiently and release less pollution and drinking water is cleaner. Coastal communities and those around closed bodies of water also now enjoy a better quality of life with reduced pollution as the result of Dr. Stumm's efforts.

In his first and main issue, Dr. Stumm contributed significantly to understanding and addressing of eutrophication, the overfertilization that ultimately clogs lakes, rivers, and reservoirs with excessive vegetation and reduces oxygen content of the water. He showed that the main problem results from the concentration of phosphorus due to agricultural and urban wastes. The direct result of his research was that the use of phosphorus in agricultural areas was reduced and even in everyday consumer items such as laundry detergent, which used to contain much phosphorus prior to Stumm's work. His research results also resulted in the technology to remove phosphorus from wastewater and drinking water.

Dr. Stumm also studied the corrosion of materials and transmission of metal ions into the environment. This work primarily concentrated on iron and manganese cycling in aquatic systems. This cycling is very complex, with ions, reactive particles, and algae and aquatic organisms all playing a role. The results of this research have been applied to many common problems such as acid precipitation, acid mine drainage, the transport of particle reactive pollutants into lakes and reservoirs, and the removal of iron and manganese from drinking water. As a result, our drinking water is cleaner, there are new regulations on acid contents of air and water, and lakes and reservoirs are cleaner.

Werner Stumm introduced a new holistic approach to water chemistry and, with his protégé, James Morgan, wrote the seminal textbook *Aquatic Chemistry*, which has sold more than 40,000 copies. In this book and in his 15 others and more than 300 professional articles, Stumm developed environmental chemistry to the level of the most advanced chemical research. The work and dissemination thereof advanced other scientific disciplines that overlap water chemistry, such as limnology, oceanography, ecology, soil science, and environmental engineering, and Stumm participated in much of the transference and even the basic research. As an example of how far-reaching his work is, he has one professional article that has been cited more than 1,000 times in other articles. As a result of his steadfast concern

that his results benefit others, all these disciplines are much more effective, and our environment in all of these areas is greatly improved.

After alleviating many of the main water pollution issues through detailed research, Dr. Stumm would seem to have every reason for optimism that humans could overcome all environmental problems given time and interest. This, however, was not the case. Instead, he issued stern warnings that measures to isolate and protect the environment such as air cleaning and wastewater treatment plants will not significantly slow its destruction. The ever-increasing population density, coupled with the high economic and technological demands of lifestyles in industrial nations, will continue to cause significant pollution and continue to impair the Earth's environment. Dr. Stumm warned that population growth must be halted during the course of the next two generations, and the consumption of goods and resources must be controlled. Otherwise, Stumm warned, "the heightened expenditure of energy will progressively disturb (the Earth's) hydrogeological cycles and call into question the preservation of our life support systems."

### BIOGRAPHICAL INFORMATION

Werner Stumm was born on October 8, 1924, in Wolfhalden, Switzerland, where he spent his childhood. He attended the University of Zurich, where he was awarded his Ph.D. in 1952 with a dissertation on inorganic chemistry. He then obtained a position on the staff of the chemistry division at the Institute for Water Resources and Water Pollution Control at the Swiss Federal Institute of Technology in Zurich, where he first encountered problems of water pollution. Stumm applied for and was awarded a postdoctoral fellowship at Harvard University in 1954 in the Department of Engineering and Applied Physics. He performed so well as a postdoctoral fellow that he was asked to join the faculty at Harvard University in 1956 as an assistant professor of sanitary chemistry. By 1961, Stumm was awarded the prestigious position of Gordon McKay Associate Professor of Applied Chemistry and in only three more years the Gordon McKay Professor of Applied Chemistry. It is rare that any associate professor can be promoted to full professor in three years; at Harvard University it is nearly nonexistent. In 1968, Werner Stumm finally became a U.S. citizen.

No sooner had Stumm changed citizenship than he was offered a prestigious position back in his home country of Switzerland. Even more enticing was that it was a professorship and the director position at the Institute for Water Resources and

Water Pollution Control at the Swiss Federal Institute of Technology in Zurich, where he had begun his career 18 years earlier. He accepted the position in 1970 and remained there for the rest of his career, until 1992. During that time, he built up the Institute for Water Resources and Water Pollution Control with some of the best environmental scientists in the world through his reputation and abilities. He posed the research questions that became the major efforts and accomplishments. As a result, it went from being a decent research institute to, without argument, the preeminent environmental research lab in the world. He was so generous with his time and energy with his students and colleagues that he was referred to as “father doctor” by the many people he mentored.

Werner Stumm retired in 1992 and moved to Kusnacht, Switzerland, but remained active in scholarship. He died at his home on April 14, 1999.

### RECOGNITION AND AWARDS

The research accomplishments of Werner Stumm were well recognized by the research community of the world with the awarding of numerous prestigious honors and prizes. He received the Monsanto Prize for Pollution Control in 1977 from the American Chemical Society, the Albert Einstein World Award of Science in 1985 from the World Cultural Council, the Tyler Prize for Environmental Achievement in 1986, the Simon W. Freese Award in 1991 from the American Society of Civil Engineers, the Goldschmidt Medal in 1998 from the Geochemical Society, and posthumously the Stockholm Water Prize in 1999, among many others. He was awarded numerous honorary doctoral degrees from such institutions as the University of Geneva, KTH Stockholm, University of Crete, Northwestern University, and Technion. Stumm was also elected to the U.S. National Academy of Engineering in 1991.

**styrene** Some substances are used virtually every day by most people and are never thought of as potential environmental or health hazards though

they may be. This is the case with styrene, which is most commonly used to make polystyrene. Polystyrene is in foam drinking cups and food packaging, as well as a number of very common items. It is also used in numerous other common applications including all latex items. Styrene is also known as vinyl benzene, Phenethylene, Cinnamene, Diarex HF 77, Styrolene, Styrol, and Styropol. Styrene has been ranked as the 271st worst environmental threat of the 275 chemicals on the 2007 CERCLA Priority List of Hazardous Substances, and it has been found in 52 of the first 1,177 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) where it was tested. It is the properties of styrene and its metabolite, styrene oxide, that make it a health and environmental threat and why its use and release must be regulated.

### PROPERTIES, USE, AND PRODUCTION

Styrene is both naturally occurring in plants and foods including vegetables, fruits, nuts, and meats and synthesized in a laboratory. Synthetic styrene is a colorless to yellowish oily organic liquid with a strong floral odor. It is an aromatic hydrocarbon that is volatile and flammable. Styrene oxide is a colorless to straw-colored liquid with a sweet, pleasant smell. Styrene is primarily used in the manufacture of plastics, synthetic rubber, resins, and insulators through the chemical production of polystyrene (PS), acrylonitrile-butadiene-styrene (ABS), styrene-acrylonitrile (SAN), styrene-butadiene rubber (SBR), styrene butadiene latexes (SBL), and unsaturated polyester resin (UPR) (fiberglass resin). The most common products of these compounds are food and industrial packaging, insulation (electrical and thermal), adhesives, concrete products, fiberglass, pipes, automobile parts, drinking cups and other “food-use” items, and carpet backing. Other styrene products include protective surface coatings, paints, construction materials, and boat manufacture materials, and a flavoring agent for ice cream and candy. Styrene oxide is used in the manufacture of resins, surface coatings, and agricultural and biological chemicals, as well as perfume (oil of roses) and cosmetics. Smaller-scale applications include hydraulic fluids, chlorinated cleaning products, petroleum distillates, dielectric fluids, and the treatment of fibers and textiles.

The production of styrene greatly increased in the 1940s as a result of the wartime demand for synthetic rubber. By 1988, production in the United States had reached 8.5 billion pounds (3.9 billion kg), and it increased to 10.1 billion pounds (4.6 billion kg) by 1993. That year, exports were 1.6 billion

pounds (0.73 billion kg) and imports were 552 million pounds (250.9 million kg). The distribution of this consumption was 66 percent for polystyrene, 11 percent for ABS and SAN resins, 6 percent for SBR (synthetic rubber), 6 percent for SBL (latex), 5 percent for UPR fiberglass resin, and 6 percent for miscellaneous copolymers. There is not much information on the production of styrene oxide, but, in 1990, it exceeded one million pounds (454,000 kg) for the year.

### ENVIRONMENTAL RELEASE AND FATE

In addition to being released as a point source pollutant from manufacturing and storage facilities or from improper disposal, there are several nonpoint sources of styrene including tobacco smoke, automobile exhaust, oxyacetylene welding, burning of brake linings, and waste incineration, among others. Most environmental release of styrene is to air or on land. In air, styrene is mainly in vapor form and reacts quickly with ozone and hydroxyl radicals produced by photochemical reactions. The removal half-life rate is nine hours from reaction with ozone and 3.5 hours from reaction with hydroxyl radicals for a combined 2.5-hour rate, depending upon physical and chemical conditions. If styrene attaches itself to dust particles, it may persist longer and be transported great distances. If released into water, styrene evaporates quickly from the surface at a removal half-life rate of 0.6 day from streams and rivers, depending upon flow rate, and 13 days from ponds and lakes. If released to soil, styrene evaporates quickly from the surface, but, once below the surface, it is much more persistent. Removal from soil is primarily through biodegradation because it has a low mobility in soil. In one study, after 16 weeks, 95 percent of styrene had been removed from landfill soil and 87 percent had been removed from a sandy loam through microbial action. Styrene has been found in drinking water in a few instances, including the water supply of Cincinnati, Ohio, but such an occurrence is rare.

The EPA Toxic Chemical Release Inventory of 1987–93 records industrial release of more than 2 million pounds (909,090 kg) of styrene to the terrestrial environment. More than 85 percent of the release was to land (15 percent to water), and it was primarily from manufacturers of adhesive, sealant, concrete, synthetic rubber, and plastic parts and resins. The states with the highest environmental release of styrene are, in rank order, Texas, West Virginia, Indiana, Wisconsin, Ohio, Georgia, Louisiana, Florida, New York, and Kentucky. Releases into the air, however, were 34.2 million pounds

(15.5 million kg) in 1992 alone. Industrial release of styrene oxide to the environment has been less than 100 pounds (45 kg) per year since 1994.

### HEALTH EFFECTS FROM EXPOSURE

Exposure to styrene and its metabolite, styrene oxide, has been shown to produce a variety of adverse health effects primarily in animals but also in workers in styrene-based industry. Acute exposure to styrene mainly affects the central nervous system causing depression, concentration problems, muscle weakness, tiredness, and nausea. It may also result in irritation of the eyes, nose, and throat. Chronic (long-term) exposure to styrene may also damage the central nervous system (CNS) with symptoms such as headache, fatigue, weakness, depression, CNS dysfunction, hearing loss, and peripheral neuropathy, as well as damage to the liver, kidney, blood, and immune system. Increased maternal and fetal mortality rates, as well as decreased birth weights, were found when pregnant animals were exposed to styrene.

The EPA has classified styrene as a group C possible human carcinogen, and the International Agency for Research on Cancer has classified it as a group 2B, possible human carcinogen, but the styrene oxide metabolite as a group 2A, probable human carcinogen. Most of the evidence for its classification as a carcinogen is from animal tests, although one study found a link to human leukemia and lymphoma. In laboratory animals, an increased incidence of cancer of the lungs, bronchial tubes, liver, lymph glands, mammary glands, and blood (leukemia) was found as the result of exposure to styrene in a variety of animals. Styrene oxide produced tumors in the forestomach and liver of laboratory animals. It was also found to be a genotoxin, causing chromosome damage, deoxyribonucleic acid (DNA) strand breaks, DNA adducts, and mutations in numerous cell types in laboratory tests.

### REGULATIONS ON HUMAN EXPOSURE

As a result of these adverse health effects and the threat to public health, federal regulatory agencies have established limits on styrene exposure. The EPA limits styrene in drinking water to 0.1 part per million (ppm) under the Safe Drinking Water Act. They further require the reporting of the release of 100 pounds (45 kg) or more of styrene oxide. The Occupational Safety and Health Administration (OSHA) set a permissible exposure limit (PEL) for styrene of 50 ppm and a short-term exposure limit (STEL) of 100 ppm over an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health

(NIOSH) set a similar exposure limit (REL) of 50 ppm over an eight-hour day with a short-term exposure limit of 100 ppm. The immediately dangerous to life and health designation is for levels of 700 ppm or more. The NIOSH 1982–83 National Occupational Exposure Survey estimated that 108,000 workers were exposed to styrene. A recent EPA survey places the current number at about 90,000 workers.

### Sudbury mining and air pollution Sudbury, Ontario, Canada (1986–present)

**Soil Pollution** Nowhere has the connection between air pollution and ecological collapse been better demonstrated than in one of Canada's largest metropolitan areas, Sudbury, Ontario (population 120,000), located about 200 miles (322 km) north of Toronto. Sudbury includes an area of more than 1,000 square miles (2,590 km<sup>2</sup>) and is really an amalgamation of seven former separate small municipalities. The seeds of Sudbury's environmental devastation began long before the Industrial Revolution.

#### BACKGROUND

About 1.9 billion years ago, a meteorite struck the Earth 200 miles (322 km) north of Toronto. Out of this cataclysmic event, a bowl-shaped basin formed

that was some 40 miles (64.4 km) long, 20 miles (37.2 km) wide, and 10 miles (16.1 km) deep. The heat and pressure of the impact melted rocks, and minerals seeped to the surface through the fractures along the rim of this basin. These minerals formed one of the world's most important reserves of nickel and copper. Today, approximately 60 percent of all underground hard rock mining in Canada takes place within a radius of 300 miles (482.8 km) of Sudbury. There is more than 3,200 miles (5,150 km) of tunnel or drifts under the area.

The first environmental destruction of the area, however, was not caused by mining but by logging. The area around Sudbury began to be commercially logged in the early 1870s. Using the existing well-developed river system, pine and cedar were floated to Georgian Bay and Lake Huron for export to the United States. The timber from these logs was used in the rebuilding of Chicago after the Great Fire in 1871.

When permanent settlers began arriving in Sudbury a few years after logging began, large areas of forest were quickly clear-cut to make way for towns, railroads, and farms. Clear-cutting, however, left extensive amounts of scrub, leaves, branches, and small trees unsuitable for timber. Once this "slash" material dried, it created an ideal environment for wildfires, and over the next 20 years, countless conflagrations swept across the Sudbury landscape. Ironically, the timber used to rebuild after a fire in the United States created a legacy of fire for the community in Canada that supplied it.

Finally, in 1885, a surveyor for a railroad company discovered the richest deposits of nickel in the world within the meteorite impact zone. Shortly thereafter, significant deposits of copper also were found. Mining began almost immediately and continues today, more than 120 years later. The extraction and processing of these minerals, however, had environmental cost. The copper and nickel are bound up in the minerals pentlandite [(FeNi)<sub>9</sub>S<sub>8</sub>] and pyrrhotite [Fe<sub>1-x</sub>S], which are also rich in sulfur. The presence of this sulfur is a nuisance: It interferes with mineral refining and detracts from the high melting points, malleability, and electrical conductivity that make these metals valuable.

#### POLLUTION OF THE SITE

To remove the unwanted sulfur, ores were roasted in open burn pits. A mixture of ore and wood was kept burning for months in order to ready the ore for loading into a furnace for further processing. The heat and air of the roasting converted sulfur to sulfur dioxide (SO<sub>2</sub>), a major cause of acid rain. Roasting was typically used to remove sulfur until

**Ecosystem devastation near INCO nickel mine and smelter, Sudbury, Ontario, Canada, 1994** (© Paul A. Soders/CORBIS)

environmental regulations prohibiting the uncontrolled discharge of  $\text{SO}_2$  directly to the atmosphere were established.

Open air roasting in Sudbury was gradually replaced by ore processing at higher temperatures in enclosed vats or tanks inside buildings.  $\text{SO}_2$  was still emitted, but stacks distributed it across a wider area, thus diluting its effects. In 1965, a record 2.5 million tons (2.3 million metric tons) of sulfur dioxide was discharged into the atmosphere around Sudbury. In addition, as mining continued, tailings and slag began to accumulate to such a degree that by 1984, the cumulative area occupied by these waste products was more than 3,000 acres (about five square miles [ $13 \text{ km}^2$ ]) with new material added at the rate of about 8 million tons (7.3 million metric tons) per year. Modern smelting plants use gas-scrubbing systems to remove  $\text{SO}_x$  to produce sulfuric acid as a commercial by-product.

The combination of clear-cut logging, fires, mining, and ore roasting/smelting proved too much for the Sudbury ecology. The soil system disintegrated, either washing away through the lack of vegetation or becoming sterile through acidification by  $\text{SO}_2$  emissions. Soil near most roasters and smelters

became toxic as a result of the elevated levels of copper and nickel discharged into the air, which subsequently settled onto the ground. Over a larger area, aluminum, leached by acid rain from minerals in the soil and bedrock, began to concentrate in the soil and started to interfere with plant growth and reproduction.

The phytotoxic effects were widespread. By 1967, most vegetation within 40 square miles ( $103.6 \text{ km}^2$ ) of Sudbury was dead. Within 140 square miles ( $362.6 \text{ km}^2$ ), only shrubs and secondary herbaceous cover were able to grow, and signs of distressed vegetation were visible within a 1,700-square-mile ( $4,403 \text{ km}^2$ ) area. The remaining soil had an acidic pH of 2.0–4.5 and was deficient in phosphorus and nitrogen, as well as calcium, magnesium, and manganese, all of which are essential plant nutrients. Soil close to the smelters had concentrations of copper and nickel often exceeding thousands of parts per million (ppm), hundreds of times higher than regulatory limits. The landscape became a bleak, barren surface of black rock so unique that during the 1970s, National Aeronautics and Space Administration (NASA) astronauts prepared for Moon landings by training around Sudbury.

### THE CLEANUP

Local residents recognized their dependence on nickel and copper and were hesitant to protest to the companies that provided their livelihood. Gradually, however, attitudes began to change. Several half-hearted attempts at restoration had been attempted over the years. In 1947, residents of the nearby town of Copper Cliffs tried to reduce dust by planting a variety of grasses and legumes on a mine tailings pile. During the 1950s, tree stumps were removed in some areas and new trees planted in imported soil to reestablish local vegetation.

In 1969, a joint program of the Ontario Department of Lands and Forests and the Laurentia University Biology Department, known as the Sudbury Environmental Enhancement Programme (SEEP), was initiated to study ways to restore the area. Initially focused on improving soil fertility, SEEP also implemented a number of restoration projects. SEEP organized the removal of dead trees and branches from barren and semibarren areas, limed and fertilized soil, and began reforestation by planting thousands of trees.

By 1986, about 10 square miles (25.9 km<sup>2</sup>) of land was involved in some stage of reclamation. Although the goal of this effort was primarily aesthetic, with restoration concentrating on creating “green belts” along highways, neighborhoods, and in a few public parks, by 1995, the results were noticeable. More than 230,000 trees had been planted, and the number of insects, birds, and some mammals had increased measurably. Although these efforts continue today, it is still far too early to claim success. Only 30 percent of the impacted areas have been addressed, and the local ecology may take hundreds of years to regain a self-sustaining condition.

**sulfur dioxide (SO<sub>2</sub>)** When the federal government first took an interest in ensuring clean air for the citizens of the United States in 1970, six principal air pollutants were identified and efforts were made to reduce their levels. Sulfur dioxide is one of the six, and these efforts have been very successful as the levels have decreased every year since they began. The reason that SO<sub>2</sub> was of such concern is that it is the primary cause of acid rain, which is both a public health and an environmental hazard. The acidity had reached such high levels in some urban and industrial areas, most notably several cities in Japan, that being caught in the rain could result in the need for medical attention. Antiquities, especially those made of marble, in many cities were being quickly destroyed, and modern structures were not safe. Perhaps even more shocking was the discovery that the acid rain could persist long distances from the urban and industrial areas. Emissions from industrial areas in Michigan had caused acid rain to extend all the way to the Adirondack Mountains of New York. As a result, because there is no natural buffering of the acidity, 90 percent of the high-altitude lakes were found to be acidic and dead, devoid of aquatic life. This acidity is the primary reason that SO<sub>2</sub> is considered such a dangerous pollutant.

### PROPERTIES AND PRODUCTION

Sulfur dioxide is a colorless gas with a very strong and acrid odor. It can exist as a liquid under pressure. It is both naturally occurring and anthropogenic. Natural sources are primarily volcanic eruptions, and lesser amounts result from weathering of minerals, including those in coal, and microbial actions on soils and in wetlands. Depending on the year, natural emissions can dwarf anthropogenic emissions and extend into the stratosphere as well as the troposphere. Emission rates from an erupting volcano range from about 44 tons (20 metric tons) to more than 22 million tons (10 million metric tons) per day. The 1991 eruption of Mount Pinatubo injected more than 37.4 million tons (17 million metric tons) into the stratosphere in one day. Human emissions of SO<sub>2</sub> result primarily from burning or refining natural substances. By far and away, the primary sources of SO<sub>2</sub> emissions are fossil-fuel-burning electric-power generating plants, accounting for 67 percent of those produced in the United States; coal-burning plants produce 96 per-

**Flowchart showing the fate of by-products of coal and oil combustion. The sulfur branch produces several air pollutants including sulfuric acid, the primary contributor to acid precipitation.**

cent of those emissions. About 18 percent of the SO<sub>2</sub> is from industrial and residential fuel combustion including automotive emissions and home heating. Some 5 percent is from fuel combustion from all other combustion engines and nonroad vehicles, including ships, trains, and construction equipment, and 3 percent is from metal processing. All other sources produce about 7 percent of emissions.

Sulfur dioxide also has some industrial applications. It has been used as a preservative in some alcoholic drinks, especially wine and beer, and in dried fruit such as apricots because it possesses antimicrobial properties. It has been used as a fumigant for grains, grapes, vegetables, and citrus fruits. It is also used as a bleach for paper, flour, wood pulp, wicker, gelatin, glue, wool, and some textile materials. Prior to the development of chlorofluorocarbons, SO<sub>2</sub> was

used as a refrigerant. It is also used in the manufacture of some chemicals (including sulfuric acid and several fertilizers) and in metal refining, cement production, water treatment, and food processing. These applications are and were relatively minor.

### ENVIRONMENTAL RELEASE AND FATE

Release of SO<sub>2</sub> into the environment causes extensive damage in a number of areas. The most damaging of these effects is acid rain. When released into the air, sulfur dioxide reacts with water and other compounds to form sulfuric acid, sulfurous acid, sulfur trioxide, and sulfates. In addition to the Adirondacks, acid waters as the result of acid rain have been found throughout the Upper Midwest, the central Appalachians, Florida, and many isolated areas in the eastern United States. Acid precipitation as rain, snow, fog, and dry particles has damaged higher-elevation trees from Maine to Georgia, reducing reproduction and making them susceptible to disease and infestation. Even at lower elevations, vegetation, including commercial crops, is adversely affected by the acidity. Runoff from this precipitation strips away nutrients from the soil, further compromising forest and farmland productivity. Once the acid reaches surface water bodies, it lowers the pH to the point where native aquatic species can no longer survive. In Virginia, 6 percent of the streams can no longer support native trout populations, and 50 percent of the remaining streams have severely reduced capacity. In Pennsylvania, the situation is even worse with regard to trout.

Sulfur dioxide also forms particles of sulfates and other compounds in the atmosphere. They scatter incoming sunlight, producing haze and reducing visibility. SO<sub>2</sub> accounts for 50 percent of the reduction of visibility in the eastern United States. These SO<sub>2</sub> aerosols reflect back enough sunlight to cause global cooling. After intense volcanic eruptions such as Tambora and Krakatoa in Indonesia and Mount Pinatubo in the Philippines, the global temperatures decreased significantly as a result of the high-altitude sulfur aerosols.

Some 31.2 million tons (14.2 million metric tons) of sulfur dioxide was released in the United States in 1970. As the result of stringent regulations, it had decreased to 25.9 million tons (11.8 metric tons) by 1980 and 23.6 million tons (10.7 million metric tons) by 1990. In the mid- to late 1990s, the releases ranged from about 18.5 to 19.5 million tons (8.4 and 8.9 million metric tons) with more than 13 million tons (5.9 million metric tons) from power-generating utilities. The reported industrial release for 2005

was 158 million pounds (71.8 million kg). It would appear that SO<sub>2</sub> emissions would have decreased on a worldwide basis, but the 33 percent decrease in emissions from the United States has been offset by a 27 percent increase in SO<sub>2</sub> emissions in China.

Clearly, the vast majority of sulfur dioxide emissions are as nonpoint source pollutants released to the atmosphere. Sulfur dioxide does, however, form a point source pollutant from some industry and waste disposal sites. Sulfur dioxide has been identified in at least 16 of the first 1,467 EPA-designated Superfund sites on the National Priority List.

### HEALTH EFFECTS FROM EXPOSURE

Acute exposure to SO<sub>2</sub> can irritate the nose, throat, eyes, and lungs and cause coughing, shortness of breath, stomach pain, headache, dizziness, nausea, fever, vomiting, serious skin and eye burns, convulsions, pulmonary edema, and death by obstructed air passages and respiratory depression with increasing concentrations. Noticeable symptoms begin at five parts per million (ppm) within 5–15 minutes, burns begin at 20–50 ppm, and death occurs within 10 minutes at 1,000 ppm. Long-term chronic exposure can cause permanent lung damage including emphysema, chronic bronchitis, and other respiratory illness; inhibition of thyroid function; loss of sense of smell; menstrual disorders; decreased fertility in men and women; and premature death. SO<sub>2</sub> is especially dangerous to people who have asthma, heart disease, and lung disease, as well as children and elderly adults. Even low doses may cause life-threatening reactions. Studies have shown a direct correlation between high SO<sub>2</sub> levels in major cities and increases in hospital admissions by as much as 10 percent. Although some studies suggest that SO<sub>2</sub> may cause increased incidence of lung cancer in laboratory animals, the EPA has placed it in group D, not classifiable as a human carcinogen, as has the International Agency for Research on Cancer (group 3).

Sulfur dioxide readily reacts to form sulfates both in natural settings and in the workplace. Sulfates and related compounds can produce acute effects of upper respiratory tract irritation, coughing, choking, difficulty in swallowing, and nosebleeds, leading to constriction of the bronchial tubes and difficulty in breathing within five to 15 minutes. Longer-term exposure may produce chest pain, laryngitis and laryngeal edema, chemical bronchitis and pneumonia, damage to the eyes, pulmonary edema, cyanosis, asphyxiation, and death by respiratory depression and failure.

### REGULATIONS ON HUMAN EXPOSURE

Exposure to sulfur dioxide is regulated by federal authorities to protect public health and that of workers. The U.S. Environmental Protection Agency (EPA) set its long-term (one-year average) air quality standard at 0.03 ppm and the short-term limit (24-hour period) at 0.14 ppm, which should not be exceeded more than once per year. The Occupational Safety and Health Administration (OSHA) set a permissible exposure limit (PEL) for sulfur dioxide of 5 ppm over an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set an exposure limit (REL) of 2 ppm over a 10-hour day with a short-term exposure limit (STEL) of 5 ppm. The immediately dangerous to life and health (IDLH) designation is for levels of 100 ppm or more. The U.S. Department of Labor estimated that more than 600,000 Americans were occupationally exposed to sulfur dioxide in 1977. The World Health Organization recommends a maximal exposure of 0.175 ppm of SO<sub>2</sub> for periods of 10 minutes or more and 0.04 ppm for periods of 24 hours or more.

In an effort to reduce acid rain, the EPA implemented a program to reduce SO<sub>2</sub> emissions by 10 million tons (4.5 million metric tons) between 1980 and 2010. As part of the program, coal-fired power plants were targeted in two phases; the first began in 1995 and the second in 2000. The first phase addressed plants with the highest emissions and the second addressed smaller plants. Older plants were grandfathered by the EPA during the first part of the project and were consequently used so heavily that sulfur emissions actually increased from 1992 to 1998, but the second phase restricted their use. The most common method of SO<sub>2</sub> reduction uses a device called a scrubber.

**sulfur oxide control technologies** Most of the electricity people rely on to maintain the economy and sustain their generally high standard of living is produced through the burning of fossil fuels including coal, oil, and natural gas. The combustion of these fuels, however, exacts a high environmental price in terms of air quality. In addition to NO<sub>x</sub>, the other major air contaminant that is emitted from the incomplete burning of fossil fuel is sulfur oxide, or SO<sub>x</sub>.

Sulfur oxides are a group of colorless gases formed when sulfur is joined with oxygen. This takes place through combustion of fuels containing sulfur, gasoline extraction from oil at refineries, and metal extraction from ore in smelters. The *x* in SO<sub>x</sub> can stand for either 2 or 3, depending upon how the sulfur reacts with gases in the atmosphere once it is released from a stack or vent. Of the sulfur compounds created during combustion, sulfur dioxide (SO<sub>2</sub>) is the most important. It is a colorless gas that can usually be noticed by either smell or taste at concentrations between 0.3 part per million (ppm) and 1 ppm. At concentrations above about 3 ppm, it has a pungent, irritating odor. The main reason to control SO<sub>x</sub> emissions is that both compounds react with oxygen in the atmosphere to form sulfuric acid:

The amount of SO<sub>x</sub> emitted during combustion is related directly to the sulfur content of the fuel. Approximately 95 percent of the sulfur in combusted fuel is discharged as SO<sub>2</sub>. Between 1 and 5 percent combines with oxygen to form SO<sub>3</sub>. Sulfur particulate, which is regulated as particulate matter with a diameter of 10 microns or less (PM<sub>10</sub>), makes up 1–3 percent of the exhaust gas. Sulfur dioxide emissions are regulated by three National Ambient Air Quality Standards (NAAQS) at an annual average of 0.03 ppm (80 mcg/m<sup>3</sup>), a 24-hour level of 0.14 ppm (365 mcg/m<sup>3</sup>), and a 3-hour level of 0.50 ppm (1,300 mcg/m<sup>3</sup>).

This means emissions of gases from smokestacks cannot have average concentrations of sulfur dioxide higher than these values. The first two standards, annual average and 24-hour level, are called public health, or primary, standards. The three-hour level is a secondary aesthetic or quality-of-life-related standard. The annual average standard cannot be exceeded even once, whereas the two shorter-duration values cannot be exceeded more than once per year. Sulfur dioxide is used as the criterion pollutant, the indicator of how much sulfur oxide is present in the air. One of the most dramatic examples of effects of exposure to excessive levels of SO<sub>x</sub> on human health occurred in 1930 in the Meuse Valley, Belgium.

In the United States, the major producers of SO<sub>x</sub> are electric utilities, particularly those that burn coal. About 15 million tons (13.6 million metric tons) of SO<sub>x</sub> is released into the air every year through the generation of electricity by burning coal. Industrial facilities that process raw materials from metallic ores, coal, and crude oil, or that burn coal or oil to produce heat, also contribute to atmospheric SO<sub>x</sub>. These include such economically essential activities as petroleum refining, cement manufacturing, and metal processing. Locomotives, large ships, and some construction equipment burn diesel fuel that has high-sulfur content and release SO<sub>x</sub>.

## CONTROL METHODS

There are several technologies available to control SO<sub>x</sub> emissions. Until the early 1960s, SO<sub>x</sub> emissions were managed primarily through dispersion. A tall stack or chimney was built and SO<sub>x</sub> emissions discharged well above the land surface to prevent the area immediately adjacent to the source from being affected. All this did was to transfer the problem to other areas as the acid rain formed by the SO<sub>x</sub> eventually landed on farmlands, watersheds, and buildings far from where it was released. Air quality standards developed and enforced over the last 30 years are much more stringent and cannot be met by simply transferring the pollution to another area.

Modern SO<sub>x</sub> reduction methods can be broadly grouped into three categories: the use of low-sulfur fuels, removal of sulfur from fuel prior to combustion (fuel desulfurization), and removal of sulfur from the waste gases after fuel combustion (flue gas desulfurization, or FGD).

### Low-Sulfur Fuels

The amount of sulfur in vent or stack emissions is related directly to the sulfur content of the fuel.

Many industries have elected to switch to fuels that contain very low concentrations of sulfur. Regulations by the U.S. Environmental Protection Agency (EPA) require the use of ultralow sulfur diesel fuel (<15 ppm sulfur) for all cars, trucks, buses, and other vehicles since 2006. Many refiners introduced this type of fuel earlier than required, and several states (especially California) developed programs that financially encouraged the early introduction and use of these types of fuels. Burning fuels containing minimal amounts of sulfur significantly lowers SO<sub>x</sub> emissions, eliminating the need to install and maintain expensive air pollution control equipment. Ultralow sulfur fuel, however, is expensive, and its use may require major modifications to plant or facility equipment.

### Fuel Desulfurization

Another way to manage SO<sub>x</sub> emission is to remove the sulfur before the fuel is burned. This process, called desulfurization, is used primarily for coal- and petroleum-based fuels. The sulfur in coal is

present in two forms; it can be chemically bound with the carbon, called organic sulfur, or it can occur as a mineral impurity, called inorganic sulfur. The mineral pyrite (FeS<sub>2</sub>) is the most common form of inorganic sulfur and forms as the organic matter (primarily plant material) is compressed and changed into coal.

Swamps or wetlands that collect organic matter in drier climates commonly contain bacteria that accumulate sulfur and iron. These elements combined to form pyrite as the organic matter was converted into coal. Organic sulfur can only be separated from coal during or after combustion, but inorganic sulfur can be removed during “coal cleaning.”

After mining, almost all coal is processed or cleaned to remove ash-forming minerals and moisture, because they increase transportation costs and reduce burning efficiency at power plants. Ash-forming minerals are impurities consisting of silica, iron, aluminum, and other incombustible matter contained in coal. Coal cleaning, the removal of ash-forming materials, has the added benefit of removing

**Diagram of a sulfur oxide removal system, or “scrubber” for exhaust gases emitted by tall smokestacks. The primary removal mechanism is the reaction of sulfur oxides with lime to produce calcium sulfate.**

## SOME COMMON FUELS AND THEIR AVERAGE SULFUR CONTENT

Fuel	Sulfur Content (weight percent)	Sulfur Content (ppm)
Natural gas	0–0.0007	0–7
Kerosene	0.04–0.3	400–3,000
Gasoline	0.02–0.06	200–600
Diesel fuel (No. 1)	<0.1–0.6	<1,000–6,000
Diesel fuel (No. 2) heating oil	0.6–6	1,000–6,000
Diesel fuel (No. 6)	1–4	10,000–40,000
Coal—western	0.06–0.4	600–4,000
Coal—eastern	3–5	30,000–50,000

pyrite and, therefore, reducing the formation of SO<sub>x</sub> in stack emissions.

Coal cleaning begins with the crushing, grinding, and screening of the material into coarse, intermediate, and fine fractions. The crushing frees ash-forming minerals and pyrite, and grinding results in better physical separation of these materials from the coal. Separation is carried out by hydrocyclone, dense-media, or froth flotation techniques.

Hydrocyclones separate coal from impurities by centrifugal force. The technique is based on the relative density differences between the heavier ash-forming materials and pyrite and the lighter coal. The pulverized coal is mixed with water to form slurry that is fed into a cylinder that has an airstream blowing up through its center. As the slurry circulates, the heavier impurities settle to the bottom, forming a refuse bed, while the air dries and transfers the lighter coal, forcing it into a storage bin.

Dense-media separation technologies also rely on density differences. Instead of using water and air as the separation medium, the pulverized coal is mixed with a fine, heavy mineral. This results in slurry with an average density between those of the heavier impurities and the lighter coal particles. The slurry is fed into a settling tank where the coal rises to the surface and is separated while impurities sink to the bottom. In many applications, a cyclone is used to supply centrifugal force to speed material separation. The separation medium is captured by a strong magnet and recycled. A wide range of coal sizes can be processed by varying the density of the separation medium.

Froth flotation is a coal cleaning process that utilizes the difference in surface characteristics between coal and the ash-forming minerals and pyrite. The coal is pulverized and mixed with water, but, in this case, soap is also added. Air is bubbled through the mixture, and the difference in the density between

the air bubbles and water provides buoyancy that lifts the coal to the surface in a froth that is then skimmed. This procedure is costly and complicated, requiring a high degree of maintenance during operation, and is used principally for metallurgical coal, a grade of coal used for making coke. Coke is produced by partially burning coal in a low-oxygen atmosphere. This leaves a solid that burns at a higher temperature than regular coal. There are two types of coke. Chemical grade coke is used in the production of calcium carbide. Metallurgical grade coke produces a much higher temperature and is used as the heat source in blast furnaces for making steel.

Removal of sulfur from petroleum fuels such as kerosene, gasoline, and diesel is more complicated and takes place as part of the refining process using hydrodesulfurization, also called hydrotreating. Hydrodesulfurization (HDS) is done at temperatures greater than 700°F (371°C), and at pressures exceeding 150 pounds per square inch (10.1 bars). HDS was first used during World War II to meet the demand for very low-sulfur aviation fuels. Today, EPA regulations and those in the European Union require a 90-percent reduction of sulfur content in automotive fuels over previous levels.

HDS entails passing the crude petroleum through a catalytic treatment bed in the presence of hydrogen. This converts the sulfur compounds to hydrogen sulfide. The hydrogen sulfide is then chemically separated, converted to elemental sulfur, and removed. HDS was initially considered the sulfur reduction technology of choice because of the ready availability of reformat, a hydrogen-rich gas produced during petroleum refining using alcohol or hydrocarbon. Hydrogen is expensive to make by itself, and because of this, most refineries recycle the reformat generated by their other activities into HDS processes.

## OTHER TYPES OF WET SCRUBBER SYSTEMS

Scrubber type	Description	Uses
Spray chambers	The simplest, lowest-energy, and most cost-effective type of scrubber. Flue gas is discharged into a chamber, where it is sprayed with water or scrubbing liquid. The scrubbing liquid surrounds the particulate, washing it to the bottom of the chamber. A cyclonic chamber is sometimes used to induce a twisting motion to the gas stream. This motion results in higher gas velocities and more efficient interaction between the particulate and scrubbing liquid.	Removal efficiencies range from 80 to 99 percent for SO <sub>2</sub> , depending upon the type of scrubbing liquid and tower design.
Packed bed	Flue gas is discharged into a vertical or horizontal cylinder that is packed with nonreactive material of a specific shape. Water or scrubbing liquid is introduced at one end of the cylinder opposite to the gas flow and coats the packing material. As the waste gas contacts the packing material, particulate is trapped by the scrubbing liquid and is collected for separation and disposal.	Clogging is common in these types of systems, and they are typically limited to waste gas streams with low particulate concentrations. They are not an effective primary SO <sub>x</sub> control technology
Impingement Plate	This scrubber consists of a long, hollow cylinder filled with horizontally mounted perforated plates. The waste gas is forced upward from the bottom of the cylinder while the scrubbing liquid drips down through the plates. As the liquid has contact with the gas stream, it entraps particulate matter, washing it downward into a collection tank.	Used primarily for collection of larger particulate. Cannot be used as a primary SO <sub>x</sub> management device.
Mechanically aided	Waste gas is directed into a high-speed fan into which water or scrubbing liquid is sprayed. The impact of the water on the fan forms fine droplets that interact with and capture particulate in the gas stream. This liquid is then collected and the particulate allowed to settle out.	Energy intensive and requiring a high degree of maintenance, mechanically aided scrubbers are infrequently used for either particulate or SO <sub>x</sub> control.

## Flue Gas Desulfurization

Even after coal cleaning or HDS, it may be difficult for some stack emissions to comply with current SO<sub>x</sub> limits. The next step is to reduce sulfur content in stack gas, after the fuel has been burned. This is called flue gas desulfurization (FGD), and these technologies can be classified as wet, semidry, or dry processes.

Wet FGD processes spray alkali slurry into the flue gas, forming a weak acid solution that is neutralized by the dissolved alkali. Sulfite and sulfate salts precipitate and are recovered for disposal or sale. In dry FGD systems, either the alkali is mixed into the gas stream or the gas stream passes through a bed of very fine and porous material. SO<sub>2</sub> reacts directly with the solid alkali to form sulfite or sulfate. Water is sprayed into the flue gas in semidry systems. A liquid film forms on the material into which the SO<sub>2</sub> dissolves.

FGD systems can be further subdivided as once-through or regenerable processes. Once-through FGD systems are more commonly used and produce a waste product that must be disposed of properly. Regenerable FGD changes the recovered SO<sub>x</sub> into a useful industrial product, such as elemental sulfur or sulfuric acid. FGD systems are typically used on large electricity-generating boilers. For smaller industrial boilers, the use of low-sulfur fuels is usually a more cost-effective method of reducing SO<sub>x</sub> emissions.

## Once-Through (Nonregenerable) FGD Systems

There are four commonly used nonregenerable FGD systems, three that rely on scrubbing vapors and one that utilizes an absorption process to remove sulfur. Scrubbers work particularly well on SO<sub>x</sub> because sulfur dissolves in water.

Wet lime scrubbers, also called limestone scrubbers, are the most commonly used nonregenerative

Scrubber type	Description	Uses
Venturi (also called gas-atomized spray scrubber)	Flue gas is mixed with water and forced through a small orifice (the venturi) that forces it to accelerate as the orifice narrows and then expand as it widens. This atomizes the mixture and allows the scrubbing liquid to surround and encapsulate the particulate matter. After passing through the venturi, the liquid is separated from the particulate in a cyclone or with a mist eliminator.	Venturi scrubbers are used in applications where high collection efficiencies for fine particulate are necessary. They also are capable of control of volatile organic compound (VOC) and SO <sub>x</sub> emissions.
Orifice (also called entrainment or self-induced spray scrubbers)	The exhaust gas stream flows over the surface of and picks up droplets of the scrubbing liquid. The moist waste gas is directed upward through a duct into a narrow orifice. This causes turbulent flow, atomizing or reducing the size of the entrained droplets. The atomized droplets soak up the particulate matter. Condensate baffles remove the droplets and drop them into a collection tank.	Designed primarily to control fine particulate matter with a diameter of 10 microns or less (PM <sub>10</sub> ). Sox control is a secondary benefit.
Condensation (also called growth scrubber)	Exhaust gas is saturated with water and injected with steam. This creates a supersaturation condition, and the particulate matter serves as condensation nuclei for the excess water vapor. The condensed droplets, which contain the particulate matter, are then removed by a series of baffle plates, a mist eliminator, or similar device.	Installed and operated at facilities to capture particulate that eludes past conventional control devices. Sox control is a secondary objective of this technology.
Charged	These scrubbers impart a positive or negative electrical charge to SO <sub>x</sub> and other particulate in the flue gas. The droplets in the scrubbing liquid are given the opposite charge.	Developed primarily for the collection of fine particulate. Not often used in SO <sub>x</sub> emission management systems.
Fiber bed	Flue gas is sprayed with the scrubbing liquid and passed through layers or mats of fibrous material. The mats or fiber beds capture precipitated particulate and SO <sub>x</sub> . They are often back-washed with the scrubbing liquid to rinse captured particulate out of the fiber beds.	Most often used as a mist eliminator to capture vapors and liquids present in the flue gas rather than to control SO <sub>x</sub> . Unless they are coarsely woven, the mats or beds tend to clog, easily when used to capture solid particulate.

FGD system. Crushed limestone (CaCO<sub>3</sub>) or the more reactive and dangerous lime (calcium oxide) is mixed with water at a concentration of about 10 percent and sprayed into the combustion gases as they leave the burner or furnace and enter a large tank called a spray tower or absorber. The calcium reacts with the SO<sub>x</sub> to form calcium sulfite (CaSO<sub>3</sub>) or calcium sulfate (CaSO<sub>4</sub>). Scrubbing usually takes place after particulate removal, to maximize the reaction rate and reduce the amount of limestone or lime needed. The semiliquid slurry drops to a reaction tank, where it is allowed to settle and thicken before the water is filtered out and the material removed. Some of the slurry can be recycled from the reaction tank and used again in the wet scrubbing process. Wet lime scrubbing can remove up to 90 percent of the SO<sub>2</sub> from most flue gases.

An interesting variation of the wet lime scrubber is a process called seawater scrubbing. Combustion

gases are passed through a tower, where they are sprayed with seawater. As the gases cool, the salts present in the seawater attract SO<sub>2</sub>. The consequently acidic seawater flows into a treatment plant where additional seawater is added to balance the pH. Air is bubbled through the treated water to oxidize the SO<sub>2</sub> to sulfate in solution and to increase the seawater's oxygen content. The seawater is then discharged. Simple and reliable, this low-cost approach can remove up to 99 percent of SO<sub>2</sub> and is especially attractive in developing countries with coastal power plants.

### Other Types of Wet Scrubbers

In addition to SO<sub>x</sub>, scrubber systems have been designed and adapted to control several types of flue gases. These include particulate, hazardous air pollutants, volatile organic compounds, and acid mists.

### Spray Dry Scrubbers

These types of scrubbers inject a fine mist of calcium hydroxide slurry into the flue gas. The hot combustion gases evaporate the water, and the SO<sub>x</sub> reacts with the slurry to form solid particles of calcium sulfite (CaSO<sub>3</sub>) or calcium sulfate (CaSO<sub>4</sub>). These particles fall to the bottom of the mixing chamber or are collected in the particulate emission control system. From 70 percent to 90 percent of SO<sub>x</sub> is removed by using spray dry scrubbers.

### Sorbent Injection

In this process, a dry or moist sorbent such as limestone (CaCO<sub>3</sub>), lime (CaO), hydrated lime (Ca(OH)<sub>2</sub>), soda ash (Na<sub>2</sub>CO<sub>3</sub>), or sodium bicarbonate (NaHCO<sub>3</sub>) is added to the furnace or stack just after the combustion chamber. It can also be mixed with the fuel prior to combustion, depending upon burner configuration. The sulfur reacts with the sorbent to form particulate that is either collected in a separate chamber or collected by the existing air pollution control equipment. This process does not require a significant capital investment and can be easily retrofitted onto existing burners. The level of SO<sub>2</sub> reduction, however, is low to moderate (40–70 percent), and the amount of sorbent needed is relatively large. Several tons of waste (ash, spent and unused sorbent) is produced for each ton of SO<sub>x</sub> removed. This process is considered to be best suited when used in conjunction with low-sulfur coal at older power plants and industrial burners that need only modest levels of SO<sub>x</sub> control.

### Regenerable FGD Systems

Nonregenerable FGD systems are known as throwaway systems. It is more cost-effective simply to discard or limit the scrubbing liquid to a single pass through the system, rather than trying to capture and reuse or recycle it. Regenerable systems, however, use expensive sorbents in the scrubbing liquid, which need to be recovered. This is done by separating the sulfur oxides from the scrubbing medium and using the collected sulfur as a raw material in a commercial product such as sulfuric acid, gypsum, sulfur-based fertilizer, or even elemental sulfur. Although regenerable systems have higher capital and operating expenditure than throwaway systems, there are lower waste disposal costs and revenues from the sale of the recovered sulfur.

Regenerable FGD systems produce an off-gas stream that must be treated in order to remove the sulfur and recover the sorbent. There are about two dozen regenerable FGD technologies commercially

available; they can be generally divided into the following four major groups.

### Aqueous Alkaline Scrubbing

Although limestone (Ca) is the most common scrubbing medium, rather than alkaline metals, aqueous alkaline scrubbing is a postcombustion sulfur control in which the waste gases are scrubbed with a chemical. This method produces slurry that absorbs the SO<sub>x</sub>. The slurry is then oxidized to calcium sulfate (gypsum), which can then be used in the manufacture of wallboard, as an additive to cement, or in other building trades.

The Wellman-Lord process is an aqueous alkaline scrubbing process that can achieve up to 99.9 percent sulfur recovery from combustion gases. It can be divided into two steps. First, the hot flue gases are passed through a prescrubber, where ash, hydrogen chloride, hydrogen fluoride, and SO<sub>3</sub> are removed. The now-cooler gas is mixed with a saturated sodium sulfite (Na<sub>2</sub>SO<sub>3</sub>). The sodium sulfite reacts with the SO<sub>2</sub>, forming sodium bisulfite. The bisulfite solution is collected and fed into an evaporator. Once in the evaporator, the sodium bisulfite is treated with steam to separate or regenerate the sodium sulfite, which is fed back to the flue gases. Steam treatment also releases the SO<sub>2</sub> and converts it to elemental sulfur, sulfuric acid, or liquid SO<sub>2</sub>, depending upon the design of the system.

### Organic Absorption

This is primarily an amine-and-citrate-(Na<sub>3</sub>C<sub>6</sub>H<sub>5</sub>O<sub>7</sub>·2H<sub>2</sub>O)-based process. FGD technology using sodium citrate as the scrubbing medium requires that particulate first be removed and the exhaust gas be cooled. This can be done with a venturi scrubber. The gas is then fed into a tank and mixed with a solution containing citric acid or sodium citrate. Hydrogen sulfide (H<sub>2</sub>S) is added to precipitate recoverable amounts of elemental sulfur and allow the citrate solution to be recycled.

In amine-based processes, nitrogen is the key atom and the SO<sub>x</sub> binds chemically with the scrubbing solution. Methyldiethanolamine (MDEA) and diethanolamine (DEA) are two amines that have been used in these types of systems. SO<sub>x</sub>-enriched solution flows to a tank, where the sulfur is precipitated and recovered and the amine solution captured for recirculation. A large quantity of SO<sub>x</sub> can be removed by these types of solutions, and the process can be operated for long periods without major loss of SO<sub>x</sub> removal efficiency.

Citrate and amine systems are not commonly used where high volumes of SO<sub>x</sub>-enriched waste

gases are produced such as electric utilities. They are more commonly applied at oil refineries and other places where SO<sub>x</sub> waste gas streams are present, but not in large amounts.

### Reactive Adsorption

Regenerative scrubber systems pass combustion gases through a ceramic or metal honeycomb or lattice coated with a zinc, copper oxide, or alkali metal. Honeycomb structures are used to reduce backpressures and to ensure adequate contact between the gas and reactive metal. The sulfur dioxide is absorbed onto the catalyst and is washed off using a methane-saturated water, which adds hydrogen to sulfur dioxide and forms hydrogen sulfide. The H<sub>2</sub>S formed in the hydrotreating process is then combined with additional sulfur dioxide to produce elemental sulfur.

Hydrogen sulfide occurs naturally in crude oil and natural gas, and its removal is a critical step in the refining process. This is most frequently done by converting the H<sub>2</sub>S into elemental sulfur. Approximately 65–70 percent of the sulfur is recovered. Therefore, two or more catalytic stages are used in series, with each stage recovering one-half to two-thirds of the incoming sulfur. The number of catalytic stages depends upon the level of recovery required, with about 95–97 percent recovery possible. Most modern plants are built with two to three catalytic stages. From the condenser of the final catalytic stage, the combustion gases, containing H<sub>2</sub>S, SO<sub>2</sub>, sulfur vapor, and traces of other sulfur compounds, pass to some form of treatment, usually a wet scrubber.

### Physical Adsorption (Activated Carbon)

This method involves passing the exhaust gas through a bed of activated carbon. The carbon captures and removes the sulfur and other impurities from the gas. This process can remove up to 95 percent of SO<sub>2</sub> and more than 80 percent of NO<sub>x</sub>. It can be used alone or in conjunction with other FGD systems and has been successfully applied on a commercial basis in Europe and Japan for SO<sub>x</sub> and NO<sub>x</sub> control of emissions from coal combustion and waste incineration. A strong advantage of activated carbon is that it captures nearly all impurities present in combustion gases including particulates, SO<sub>2</sub>/NO<sub>x</sub>, mercury, lead, and dioxins. Its main drawback is the high cost associated with the chemical or physical regeneration of the carbon after it has become saturated with recovered contaminants and the recovery of the sulfur. Although carbon is the most commonly used adsorbent, alu-

mina, zeolites, and polymers have been used successfully in other systems.

**Superfund sites** On December 11, 1980, President Jimmy Carter signed the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), which had previously been passed by the U.S. Congress. The bill was written largely in direct response to the Love Canal, New York, environmental disaster, but that was really just the last straw in a growing public response to the numerous environmental disasters throughout the United States. CERCLA directed the EPA to develop the Superfund program, which would address abandoned, accidentally spilled, or illegally dumped hazardous wastes that pose a threat to the environment and human health. Superfund was designed to manage emergencies that attracted national attention—such as at Valley of the Drums; Bullitt County, Kentucky; and the Chemical Control Corporation explosion in Elizabeth, New Jersey—and also less prominent situations involving malingering and dangerous pollution. In addition, Superfund was responsible for conducting research on the processes of pollution migration; developing new technologies to treat, store, and dispose of wastes; and involving communities near hazardous

sites in the processes of delineation and remediation of the sites.

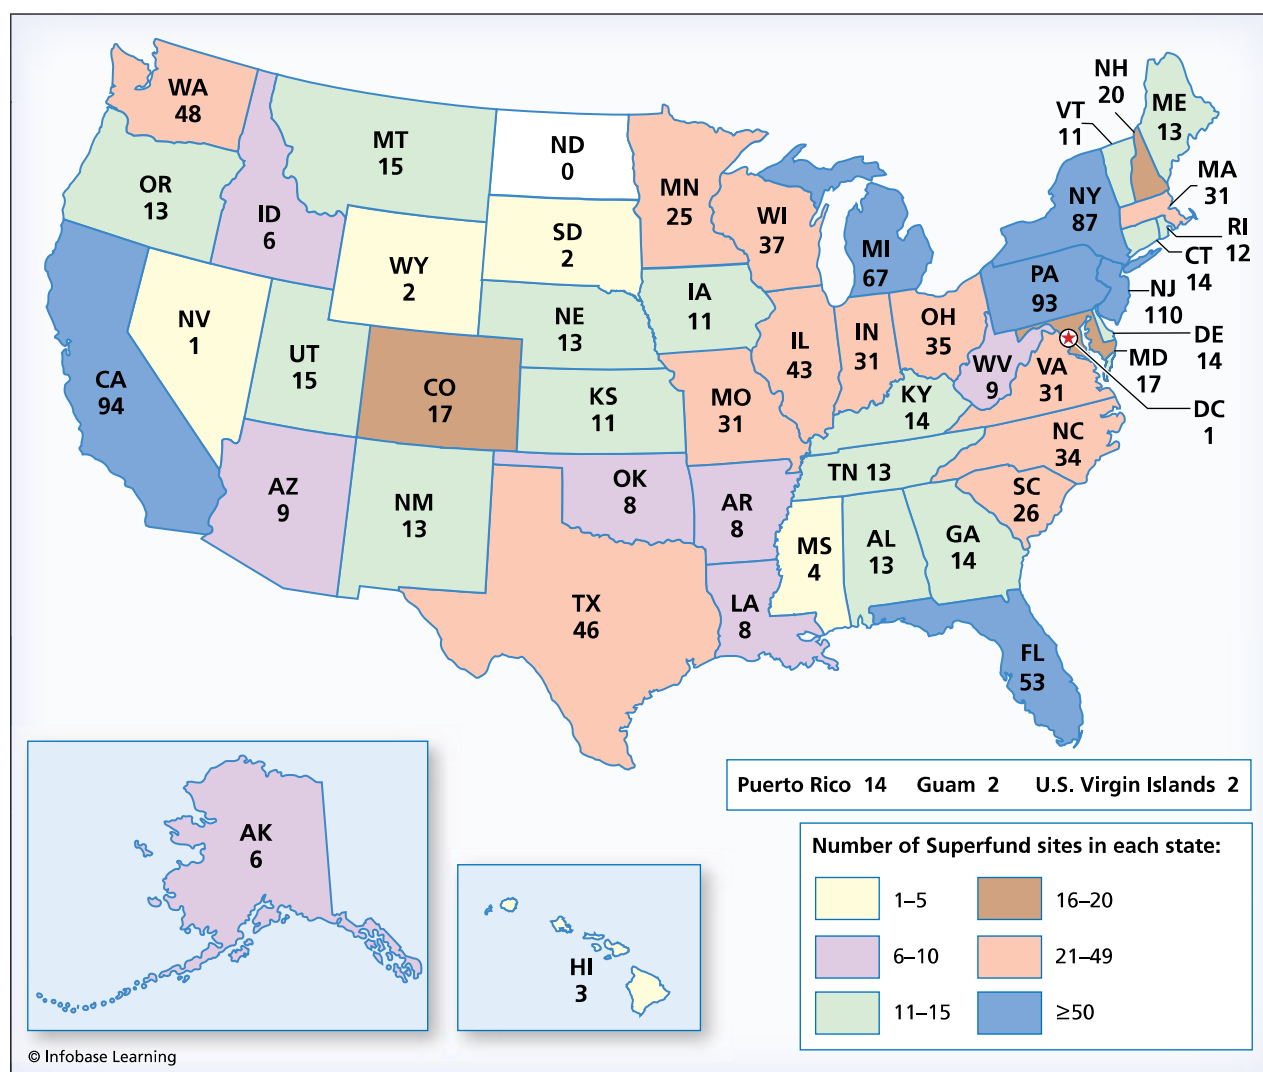

The remediation of sites with severe pollution problems is very expensive. One of the main functions of CERCLA was to create a tax on the chemical and petroleum industries to raise funds to respond to the releases or potential releases of hazardous substances to the environment. Over the first five years, more than \$1.6 billion was collected and placed in a trust fund to clean up the identified hazardous waste sites (Superfund sites). That trust fund was increased to \$8.5 billion through the Superfund Amendments and Reauthorization Act (SARA), an amendment of CERCLA that was passed on October 17, 1986. In addition, the EPA established an enforcement program as part of

Superfund that secured nearly \$24 billion in the first 25 years through seizures of assets and fines.

### CERCLA AND SARA

The original CERCLA bill of 1980 had three main functions:

1. to establish regulations for closed and abandoned hazardous waste sites
2. to establish liability for the parties responsible for releasing hazardous waste
3. to establish a trust fund to remediate sites where no responsible party exists

**Map of the United States showing the number of active Superfund sites by state in 1992** (*New Jersey was and is the state with the most sites*)

CERCLA further authorizes two actions depending on the nature of the problem:

1. emergency removals where there is an immediate threat to human health and the environment
2. long-term remediation to reduce permanently the dangers from the release or potential release of hazardous waste that does not pose an immediate threat

These sites must be listed on the EPA National Priorities List (NPL) prior to remediation. The SARA bill of 1986 added several major amendments to CERCLA in addition to increasing the budget including:

1. It encouraged the development of permanent remedies and innovative technologies in the remediation of hazardous waste sites.
2. It required the Superfund program to model the other state and federal environmental regulations in their actions where appropriate.
3. It provided additional enforcement and settlement measures for violators.
4. It increased state involvement in the Superfund process.
5. It shifted the Superfund focus more strongly toward human health threats.
6. It increased the involvement of the local residents in remediation goals and procedures.

### ESTABLISHING A SUPERFUND SITE

The EPA has established a Hazard Ranking System (HRS) to evaluate whether a particular site should be placed on the National Priorities List (NPL), which makes it a Superfund site. The HRS does not determine priority; it simply assigns a score based on certain factors, which then aids the decision process. The factors in the HRS are grouped into three categories:

1. the probability that the particular site has released or will release hazardous substances into the environment
2. the quantity, relative toxicity, and physical characteristics of the waste repository

3. the number and disposition of people and sensitivity of the environment that are or would be affected by a release

Four pathways of release can be considered under the HRS:

1. groundwater release including impact on drinking water
2. surface water, including drinking water, release impacts on the food chain and sensitive environments
3. oil release including local population and sensitive environments
4. atmospheric release including local population and sensitive environments

The procedures for establishing a Superfund site are well defined. The first step entails a preliminary assessment and site inspection. The preliminary assessment is a review of the information on a site and its surrounding area to determine whether it poses a threat to human health and/or the environment. The report is either to recommend further investigation or not. If the preliminary assessment finds reason for concern, the next step is site inspection. This procedure is designed to collect the data necessary to perform scoring using the HRS. The inspection includes visiting the site to provide a full visual and quantitative analysis, including the collection of environmental and waste samples for chemical analysis. This inspection is also designed to determine whether and how far the pollution has spread from the source. The results from this analysis and consequent HRS score are used to determine whether the site should be placed on the NPL and undergo remediation.

If the site in question meets the requirements for NPL, the next step is to perform a remedial investigation and feasibility study (RI/FS); both aspects are studied concurrently. The remedial investigation is designed to characterize the site, determine the type of hazardous waste, evaluate the risk to public health and the environment, and evaluate the cost and effectiveness of the proposed treatment plan. The feasibility study evaluates alternative remedial methods and actions. Investigators must complete five distinct phases:

1. scoping
2. site characterization

3. evaluation of alternatives
4. treatability evaluation
5. detailed analysis

Scoping involves the initial physical delineation of the study area, determination of remedial objectives and any interim procedures, and determination whether the site should be parceled or treated as a single unit. Detailed scoping objectives are addressed once the broad strategies are determined. These activities typically include determining the regulations involved in the remediation Applicable or Relevant and Appropriate Requirements (ARARs), determining the course of action and data requirements to pursue it, assembling the technical advisory committee, and preparing the entire plan of action including scope of work, sampling and analysis, health and safety, and community relations.

The site characterization phase includes field sampling of water, soil, and air and chemical analysis thereof. Proper protocol calls for a preliminary site characterization report in the early stages of the study and a full remedial investigation report at the end. This phase also includes a feasibility study of the planned technology to be applied and a baseline risk assessment for both human health and the environment.

The phase of development and screening typically begins during the scoping phase as soon as the objectives of the remedial action become apparent. Once the objectives are known, treatment, recovery, and containment options to address them can be proposed. The technologies involved in these processes might then be evaluated or screened as to their effectiveness and implementation in the particular situation, as well as their cost. Finally, alternatives to the standard operating procedures are considered to optimize the remediation efforts. This phase works hand in hand with the treatability investigations phase, which is really a refinement of the former. This phase just adds supporting information to alternatives to specify them further, and it streamlines the procedures to minimize costs.

The final step is the detailed analysis, which is the true plan of action for the site. It addresses nine criteria:

1. protection of public health and the environment
2. compliance with state and federal regulations (ARARs)
3. long-term effectiveness of remediation

4. reduction of the toxicity, mobility, and/or volume of waste
5. short-term effectiveness of remediation
6. feasibility of implementation
7. cost of remediation
8. acceptance by state authorities
9. acceptance by the impacted community

### SUCCESS OF SUPERFUND

In spite of its critics, the Superfund program is considered to have been highly successful. Compared to the situation before 1980, public health is vastly better protected as a result of this program. By the end of 2006, some 1,006 Superfund sites around the United States were considered completed, 64 percent of those on the National Priorities List. At that point, there were 653 ongoing remediation projects at 414 Superfund sites. The average time required to remediate a Superfund site is 12–15 years with monitoring continuing well after remediation is complete. It is estimated that there are 4,500 sites in the United States that will make the Superfund list during the life of the program, with a projected cost of remediation of about \$75 billion. In addition to the long-term projects, there were 294 emergency response actions that addressed immediate threats in 2006 alone with a total of 4,020 between 1981 and 1996. These actions primarily involved the cleanup and removal of hazardous substances from spills and accidental releases. The remediation of many of these Superfund sites created productive properties in key urban locations, revitalizing areas that suffered because of the environmental issues. They now generate tax revenues and serve their communities. Redevelopment of these Superfund properties, in total, has generated more than 80,000 on-site jobs and an annual income of \$2.7 billion. Although the Superfund program has had its errors, in general, it is a very successful program.

**Tasman Spirit oil spill Port Karachi, Pakistan (July 27, 2003)** *Water Pollution*

Karachi, a port city northwest of the Indus River delta, is the most populous city in Pakistan and quickly becoming the most populous area in the world. A developing megacity, the Karachi metropolitan area officially has 14 million residents, but unofficial tallies estimate the population, which tripled between 1980 and 2007, as closer to 20 million. This huge number of people is packed into a little more than 1,350 square miles (3,500 km<sup>2</sup>). The explosive growth of Karachi is the result of a vibrant economy based both on heavy industry of shipbuilding, textiles, steel, oil, and chemical manufacturing, and a strong business service sector including software development, banking, and finance. As with most megacities, the energy needs of Karachi are enormous and are partially met by a nuclear-powered electricity-generating facility, wood, and some solar sources, but oil is the primary fuel. Although Pakistan has some of its own reserves, most of the oil is from other nearby Middle Eastern countries such as Iraq, Iran, and Saudi Arabia.

The harbor is the reason the economy thrives in Karachi, and the long adjoining sandy beaches provide enjoyment and relief from the long summer heat for the residents. Summer temperature extremes also are moderated by landward ocean breezes from the Arabian Sea that cool the city, blow away its air pollution, and keep the humidity low. Karachi Harbor is protected from the full effect of storms and rough water by these same beaches as well as by a series of semiencircling barrier islands, river deltas, and rocky sea cliffs, which project off the mainland and into the ocean.

It is through Karachi Harbor that Pakistan receives most of its oil, via tankers making the short trip from the Persian Gulf southward through the Straits of Hormuz and along the Iranian coast. This was the route that the Maltese tanker *Tasman Spirit* was following when it ran aground at the entrance to Port Karachi in the early afternoon hours of Sunday, July 27, 2003.

### BACKGROUND

Named after Abel Janszoon Tasman (1603–59), the Dutch explorer and the first European to discover Tasmania and New Zealand, the *Tasman Spirit* was a single-hulled 87,584 deadweight tonnage (DWT) tanker built in 1979. It was operated under a Maltese flag of convenience and was registered to the Greek company Assimina Maritime Ltd. Under charter by the government-owned Pakistan National Shipping Corporation, the ship was carrying 74,700 tons (67,800 metric tons) of light Iranian crude oil, which was scheduled for delivery to Pakistan Refinery Ltd., a government-owned oil terminal and processing center. Another 485 tons (440 metric tons) of heavy fuel oil, or Bunker C, used in the operation of the engines and other shipboard systems, was present in *Tasman Spirit*'s aft storage tanks. *Tasman Spirit* was nearing the end of its useful life, and because of the single hull and other safety issues, it had been prevented from entering U.S. and most European ports. As a result, the Pakistan National Shipping Corporation was able to negotiate an excellent charter price from the owners, and it continued to sail up and down the coast carrying oil.

### THE ACCIDENT AND SPILL

At the entrance to the shipping channel, the harbor pilot boarded *Tasman Spirit* in a driving monsoon rain. As the ship slowly entered the harbor, it was pushed out of the main shipping channel by the strong winds and waves and went aground on a sandy shoal. The harbor pilot was initially blamed for failing to keep *Tasman Spirit* on course, but he claimed that the ship was correctly positioned. The cause was the channel, which had not been dredged to its charted depth and was too shallow to accommodate a vessel of this size. Although no oil had spilled when the *Tasman Spirit* went aground, it was blocking the entrance to the harbor and represented a potentially major public safety, environmental, and economic threat.

The initial response plan to deal with the grounding was to attempt to pull *Tasman Spirit* off the shoal and return it to the main channel. The single tug assigned to the task, however, was not strong enough to move the ship. Larger, more powerful tugs were available in another harbor only a short distance away but for some reason were not requested to assist in the refloating effort. Three attempts were made in heavy rains and high winds over the next week until August 4, when it became apparent that the stress of being repeatedly shoved and rocked against the shoal was starting to affect the structural integrity of the ship.

The Karachi Port Trust (KPT), the operators of the harbor, decided to initiate a lighterage operation by transferring the oil from the grounded ship to smaller tankers. A lighter is a small, flat-bottomed barge or tanker used in the loading and unloading of ships and in transporting cargo over short distances. These smaller lighters or tankers were to take on the oil from *Tasman Spirit* and off-load it at the nearby Pakistan Refinery Ltd., the designated receiving facility. Although the KPT stated that no environmental impacts had yet occurred, it was around this time that other vessels using the harbor began to report the smell of oil in the air. By August 11, more than 22,000 tons (20,000 metric tons) of oil had been transferred from the stricken vessel, including most of its nautical fuel, the much heavier and more environmentally damaging Bunker C oil. The lighterage operation, however, was proceeding slowly, with only 6,000 tons (5,400 metric tons) every 36 hours transferred from *Tasman Spirit* to a barge, and then from the barge to a larger tanker for transport to the refinery.

By the evening of August 13, there were major cracks in the hull of *Tasman Spirit* and in order to ensure the safety of those onboard and nearby,

lighterage operations were suspended. During the evening, the *Tasman Spirit* began to groan and shudder, and, early in the morning of August 14, it split in two. Over the next four days 29,700 tons (27,000 metric tons) of oil was slowly released into the waters of Karachi Port. Another structural failure took place on August 22 and released about 220 tons (200 metric tons). On September 4, some five weeks after grounding of the *Tasman Spirit*, the final cargo hold ruptured. In all, 33,000 tons (30,000 metric tons) of oil is estimated to have spilled from *Tasman Spirit*, and the discharge of this quantity of oil in such a confined area ranks the spill as the largest crude oil release since the *Sea Empress* discharged more than 77,000 tons (70,000 metric tons) of oil along the coast in southwestern Wales.

The oil released from *Tasman Spirit* was light Iranian crude that contained a high concentration of aromatic hydrocarbons. Aromatic hydrocarbons are a class of chemical compounds that contain one or more benzene rings and have strong, pungent aromas, usually from impurities. They readily evaporate, and exposure to aromatic hydrocarbons can have significant health effects. Although crude oil is generally a mix of many petroleum compounds, this particular type of Iranian crude was made up of 34 percent light and heavy naphtha (various volatile aromatic hydrocarbon mixtures), 4 percent gasoline, and 1.4 percent sulfur. Its American Petroleum Institute (API) viscosity was  $-20^{\circ}\text{F}$  ( $-29^{\circ}\text{C}$ ), making it "thin" and readily flowable.

As *Tasman Spirit* oil entered the water, it spread rapidly and began to evaporate quickly, aided by an  $85^{\circ}\text{F}$  ( $29^{\circ}\text{C}$ ) temperature in Karachi and the monsoon winds and rains that were stirring up the normally quiet harbor waters. The area to the west of *Tasman Spirit*'s grounding contains extensive stands of mangroves and is an important habitat for sea turtles, dolphins, porpoises, and whales, as well as several species of lizards and sea snakes. More than 200 species of fish are present in these waters, and they serve as a vital component of the local economy. To the east of the leaking wreck, some 50 different types of both resident and migratory birds inhabit the area and utilize the associated tidal estuaries, river and creek systems, mudflats, and sand beaches as both nesting and feeding grounds.

### THE OIL SLICK AND CLEANUP

The majority of the oil quickly contaminated Clifton Beach, Karachi's most popular shoreline. Ten miles (16 km) of shoreline was closed, and an additional 77 square miles (200 km<sup>2</sup>) was affected by the spill.

The 300,000 people who lived within 0.6 mile (1 km) of this important stretch of coastline faced a closed and contaminated beach; black waves carrying the bodies of dead sea turtles, sea snakes, and birds; and the overpowering smell of oil. The Pakistani government responded with the aerial application of dispersants, both along the beach and onto the open waters of the harbor. The beach spraying stopped, however, when local residents complained of nausea, headaches, and other health effects from inhalation of airborne dispersants. Oil that washed onshore was scraped and bulldozed into piles, but they were often left in place for many days because a suitable land-based disposal facility for the oily waste could not be found. During periods of low tide, government cleanup crews plowed under the upper layer of oily sand along the beach so it could no longer be seen. Only about 1 percent of the oil was recovered, and the beach was not reopened until October. The cleanup proceeded more efficiently in the harbor, with booms placed around the slick and across the entrance to sensitive waterways and habitats. These devices recovered 154 tons (140 metric tons) of oil.

One of the most important aspects of the oil spill from *Tasman Spirit* was its effect on local air quality. The high temperature, strong winds, and intense waves, which increased the spread of the oil, also hastened its evaporation. The gases and vapors emanating from the oil moved landward, pushed by the normally cooling and refreshing onshore breezes. Of the almost 30,000 tons (27,000 metric tons) of oil released from *Tasman Spirit*, an estimated 12,100 tons (11,000 metric tons) evaporated and settled over the coastal residents. Concentrations of volatile organic compounds (VOCs) measured in the air downwind of the wreck ranged from 44 to almost 180 ppm and produced an odor until early September. In the United States, no standards have been set for VOCs in nonindustrial settings, but the Occupational Safety and Health Administration regulates hydrocarbon-related VOCs to levels ranging from 0.1 to 0.75 ppm. Hospitals and medical camps established by local officials treated hundreds of people for headaches, nausea, and dizziness. There were 17 schools in the vicinity closed for up to a week, and the long-term health effects on exposed residents are still being studied.

### THE AFTERMATH

An official estimate of the amount of marine and animal life killed by the oil was not made. Later studies confirmed that bottom sediments were contaminated and that elevated levels of hydrocarbons

were present in turtle eggs and the tissues of fish and other types of marine life. Fishing in the area of the spill and within an almost-six-mile (9.3-km) radius was banned for three months, and fishermen lost a substantial portion of their income that year. Yields in subsequent years were well below normal, and several studies estimated that it would be five to seven years before prespill catch volumes were restored.

Pakistan is not a signatory to the International Oil Pollution Compensation (IOPC) Fund, a 1992 agreement established as a result of the International Convention on Civil Liability for Oil Pollution Damage and funded by a small per-gallon tax on each gallon of oil handled by the member countries. The fund covers claims made by any of its 98 member states, in excess of compensation provided by shipowners and their insurers. The fund pays for cleanup, damage to property, as well as consequential and economic losses such as from fishing bans. Funding is also provided for activities to prevent or minimize pollution, such as purchasing and equipping oil spill response boats. Pakistan fined the owner of the tanker \$200,000 and submitted claims to *Tasman Spirit*'s insurance company to recover cleanup costs, but it is unlikely that there will be enough money to compensate local residents for their illnesses or loss of income as a result of the spill.

**TCA (trichloroethane)** The term *TCA* refers to 1,1,1-trichloroethane, a very common organic compound. The problem is that 1,1,1-trichloroethane is also sometimes referred to as 1,1,1-TCE, whereas TCE is really trichloroethylene. Even more confusing is that both were restricted or banned around 1989–96 because of danger to public health and the environment. It is not surprising that the two chemicals are confused, causing problems for citizens and environmental professionals alike. TCA is also known in industry as Chloroethene, Methylchloroform, Aerothene TT, Algylen, Alpha-T, Chlorten, Gemalgene, Genklene, Dowclene, Solvent 111, Trichloran, and Inhibisol. It is a widely used chemical that has been identified in 823 of the first 1,662 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priority List) where it was tested. As the result of the wide distribution of TCA and its adverse health effects, it has been ranked as the 97th most dangerous pollutant on the top 275 of the 2007 CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USES, AND PRODUCTION

TCA is a synthetic organic colorless liquid with a sharp, sweet odor that evaporates quickly. It was invented in 1840, but peak production did not occur until the mid-1950s through 1995. At that point, its production was restricted and later banned on January 1, 2002, under the terms of the Montreal Protocol because it degrades ozone. TCA was primarily used as a solvent to dissolve other compounds. It was used as a vapor degreaser for metal products, for cleaning of precision instruments, for textile processing and dyeing, and in aerosols. It is also used as a chemical intermediate in the manufacturing of certain organic chemicals such as vinylidene chloride, as a coolant and lubricant in metal cutting oils, and in home applications such as drain cleaners, spot removers, shoe polish, food packaging, photographic film, aerosol propellant, glues, and inks. There were also agricultural uses for TCA such as fumigation of strawberries and degreening of citrus fruit and as a solvent for several varieties of pesticides. In 1989, 34 percent of TCA usage in the United States was for vapor degreasing, 12 percent for cold cleaning, 10 percent for aerosols, 8 percent for adhesives, 7 percent as a chemical intermediate, and 5 percent in coatings. The remaining 24 percent was used for a variety of miscellaneous purposes.

Domestic demand for TCA was 700 million pounds (318 million kg) in 1988, 705 million pounds (320 million kg) in 1989, and 735 million pounds (334 million kg) in 1993. Worldwide production in 1988 was 735,000 tons (678,000 metric tons).

Demand and production fell off sharply in 1996 and ended completely by 2002.

### ENVIRONMENTAL RELEASE AND FATE

TCA is mainly released as a point source pollutant from spills and leaks in manufacturing and production plants, during transportation, and in storage. Once released to soil, most TCA simply evaporates because of its high volatility. That which percolates into the soil adheres well to organic matter in proportion to the organic carbon content. It does not adhere well to clays, sand, or any other particles. As a result, it readily leaches from the soil into the groundwater system, where it is frequently found. TCA is very persistent in the natural environment. In one study, after 27 weeks in subsurface soils, no degradation was observed. Even biodegradation is slow, with an estimated removal half-life of 231 days under anaerobic field conditions.

If released to water, most TCA simply evaporates. Under laboratory conditions, removal half-life by evaporation ranged from less than one hour to several hours. In natural systems, removal half-life by evaporation was three to 29 hours for rivers, 5.1–10.6 days for ponds, and 3.8–12 days for lakes. Otherwise, that which does not evaporate degrades very slowly with a removal half-life of six months or more. TCA is also relatively stable in air. It breaks down rapidly by direct photolysis in the stratosphere, where it attacks and breaks down ozone. It was primarily for this reason that it was banned.

According to the EPA Toxic Release Inventory, some 222,000 pounds (101,000 kg) of TCA was released to water and 812,000 pounds (369,000 kg) of TCA was released to land between 1987 and 1993. The largest release by far was in California, followed by Georgia, Arizona, Indiana, Virginia, and Utah. The releases resulted mostly from steel and iron production, aircraft manufacturing, and miscellaneous manufacturing.

### HEALTH EFFECTS FROM EXPOSURE

Exposure to TCA produces several adverse health effects. Acute exposure to TCA fumes causes dizziness, loss of coordination, and lightheadedness, but the symptoms disappear quickly once the chemical is removed. If the acute exposure is longer and at higher levels, symptoms may include loss of consciousness; drop in blood pressure; damage to the liver, nervous system, and circulatory system; and, in extreme conditions, even death. Chronic exposure can also cause liver, nervous system, and circulatory system damage.

## REGULATIONS ON HUMAN EXPOSURE

Federal agencies regulate worker and general exposure to TCA as the result of these health risks. The EPA limits the amount of TCA in drinking water to 0.2 part per million (ppm) under the Safe Drinking Water Act. They further require the reporting of any environmental release of 1,000 pounds (454 kg) or more to the National Response Center. The Occupational Safety and Health Administration (OSHA) restricts the amount of TCA in workplace air (PEL) to 350 ppm for an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) has set the same general exposure limit (REL) as OSHA and a designation of immediately dangerous to life and health (IDLH) for any exposure of 700 ppm in workplace air.

**TCB (trichlorobenzene)** TCB has three isomers based on the position of the chlorine atom, 1,2,3-TCB, 1,2,4-TCB, and 1,3,5-TCB. The most common of these is 1,2,4-TCB, which is also known as Hostetex L-PEC and Trichlorobenzol. The TCBs were widely used primarily in industrial applications as well as some specialized consumer applications, but 1,2,3-TCB and, to a lesser extent, 1,2,4-TCB have been phased out over the years because of the adverse health and environmental effects associated with their usage. They are still used in some specialized applications but not nearly to the degree they were in the past. Exposure may still result from the

manufacturing applications and leaking toxic landfills but also from leaking of old electrical devices where they were commonly used as coolants. 1,2,4-TCB still has many sources of exposure but is less dangerous. 1,2,3-TCB was rated number 116 of the 275 substances on the 2007 CERCLA Priority List of Hazardous Substances and 1,2,4-TCB was rated number 203.

## PROPERTIES, USES, AND PRODUCTION

1,2,4-TCB is an aromatic colorless liquid at room temperature but a rhombic crystalline solid at slightly lower temperatures (below 63°F, or 17°C), whereas 1,2,3-TCB occurs as white crystals. 1,2,4-TCB is used as both a solvent and a chemical intermediate in chemical manufacturing; as a component of dielectric fluids, transformer coolants, and lubricants; as a degreasing agent; in septic tank and drain cleaners and wood preservatives; and as a herbicide for aquatic weed control. It was formerly used as a soil treatment for termite control. 1,2,3-TCB is used as an intermediate in the production of various organic chemicals, but many of its other applications, including as a solvent for high-temperature melting products (glass, etc.), a dye carrier for polyester material, a coolant for electrical installations, and an organic insecticide for termite control, have been largely phased out.

The U.S. Environmental Protection Agency (EPA) estimates that domestic production of 1,2,4-TCB ranged from 3 million to 8 million pounds (1.36–3.6 million kg) in 1983 with 3 million pounds (1.36 million kg) of imported chemicals. Estimated global production of TCB was 15,730 tons (14,300 metric tons) in 1995.

## ENVIRONMENTAL RELEASE AND FATE

TCB primarily exists as a point source pollutant emitted directly from industry or from spills and leaks during transport, storage, and disposal. It also occurs as a nonpoint source pollutant from its use as a herbicide and pesticide, from air pollution fallout, and from leakage from common electrical devices, among other sources. TCB is released into the atmosphere through evaporation, some burning processes, and as industrial emissions. It reacts with photochemically produced hydroxyl radicals in air with an average removal half-life of 18.5 days to several months, although it may also be removed to the surface by precipitation. If released into the soil, part of it will evaporate. The remainder adsorbs strongly to the organic particles and less strongly to clay, where it has very low mobility. In sandy soils,

it may leach into the groundwater system in some cases, and it has been detected in some drinking water systems. TCB undergoes slow biodegradation as a function of temperature primarily under aerobic conditions. It may also biodegrade under anaerobic conditions with a relatively quick removal half-life of 30.5 days or less, but with a significant lag time of up to 72 days before the process begins. There are no data on the removal of TCB from groundwater.

If it is released into surface water, an appreciable amount of TCB can evaporate depending upon conditions. The removal half-life of TCB by evaporation ranges from 4.2 hours for a river to 11–22 days for seawater. That which remains readily attaches to particles and settles into the sediment, where it undergoes biodegradation. Degradation of TCB by exposure to sunlight is extremely slow (estimated removal half-life of 450 years). Actual removal half-lives from rivers range from 1.5 to 28 days. TCB has been detected in several major surface water bodies including Lake Ontario; Lake Huron; Niagara River, New York; and Grand River, Quebec. TCB can be strongly bioconcentrated in aquatic organisms with measured concentrations ranging from 51 to 2,800 times ambient levels, posing a health hazard to humans and other predatory animals. It is highly toxic to aquatic organisms.

The EPA Toxic Release Inventory of 1987–93 records the industrial release of 180,000 pounds (81,818 kg) of 1,2,4-TCB to the environment, about 87 percent of which was to water. The state with the highest release was North Carolina, followed distantly by Virginia, Georgia, West Virginia, and New York, in decreasing order. The reported industrial release was 57,704 pounds (26,229 kg) in 2005.

### HEALTH EFFECTS FROM EXPOSURE

Both 1,2,3-TCB and 1,2,4-TCB have produced significant adverse health effects in both humans and laboratory animals. TCBs are considered to be moderately toxic through both inhalation and ingestion. Acute exposure produces moderate to severe irritation of the skin (including chloracne), eyes, throat, and mucus membranes, as well as some central nervous system effects such as lethargy and dizziness. At high dosage, laboratory animals experienced damage to the liver, kidneys, adrenal glands, pancreas, and reproductive organs to varying degrees. Long-term exposure results in decreased body weight and moderate to severe damage to the kidneys, liver, spleen, reproductive organs, adrenal glands, and thyroid, as well as less severe effects to the central nervous system and immune system. Humans also developed anemia and other blood changes. When pregnant

animals were exposed to TCB, they showed the effects of exposure, but only some of the offspring showed effects. Some groups showed decreased birth weight and size and damage to the eyes.

Although TCB is not evaluated as a carcinogen by any of the major agencies, some studies suggest that it may increase the likelihood of cancer. Laboratory animals showed great increases in liver cancer and metastatic pulmonary tumors. Many of the animals died of cancer.

### REGULATIONS ON HUMAN EXPOSURE

As a result of the risk of adverse health effects and damage to the environment, federal agencies have set exposure limits for TCB. There are some regulations for 1,2,4-TCB, but the rest of the isomers remain relatively unregulated. The EPA set a maximal level of 70 parts per billion (ppb) of 1,2,4-TCB in drinking water under the Safe Drinking Water Act. They also require the reporting of any spill of one pound (0.45 kg) or more to the National Response Center. The National Institute of Occupational Safety and Health (NIOSH) set maximal levels (ceiling) of five parts per million (ppm) of 1,2,4-TCB in workplace air for a 10-hour-workday, 40-hour workweek.

**TCE (trichloroethylene)** TCE is a chlorinated hydrocarbon solvent that has been the subject of numerous severe environmental problems. It was widely considered the most effective of the chlorinated solvents from the 1930s through the 1950s, when other solvents became available. Other names and commercial names for TCE are Acetylene trichloroethylene, Algylen, Anameth, Benzinol, Chlorilen, CirCosolv, Germalgene, Lethurin, Perm-a-chlor, Petzinol, Philex, TRI-Plus M, and Vitran. Halothane replaced TCE in many medical procedures in 1956. As a result of emerging health concerns, it was slowly removed from the U.S. and international markets, when it was banned throughout most of the world from food and pharmaceutical applications. A total ban on TCE for public consumption was not achieved until the 1980s, when, surprisingly, the final usage was as an analgesic in obstetrics, and it was implicated in fetal death. The military also phased out TCE, using a total of only 11 gallons (40 L) in 2005.

Of the first 1,428 hazardous waste (Superfund) sites identified by the U.S. Environmental Protection Agency (EPA) as serious enough to be on the National Priorities List (NPL), 861 have tested positive for TCE. This is a very high percentage, and not all sites have been tested. Because of its health effects and widespread distribution, TCE has been ranked the 16th worst pollutant of the top 275 on the 2009 CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USES, AND PRODUCTION

TCE was first invented in Great Britain in the 1920s as a revolutionary replacement for chloroform and ether. TCE is a clear, colorless, nonflammable liquid that has a sweet smell and quick evaporation. It is less toxic than chloroform and less flammable than ether, and, as a result, it was used as a volatile anesthetic and analgesic in medical procedures. It also has other uses as a solvent for numerous organic compounds and as a degreaser for metal parts. It was used in a variety of applications from extraction of oils, spices, and caffeine from plant material to dry cleaning solvent. TCE has been found in some common household items such as typewriter correction fluid, paint remover, adhesive, and spot remover. In many of these items, it has been totally removed, and in others it has been reduced.

On average, as of 2006, the United States used about 100 tons (45.5 metric tons) per year.

### ENVIRONMENTAL RELEASE AND FATE

TCE is mainly released to the environment as a point source pollutant from industrial manufacturing, transportation, and storage as spills or leaks, although it has been purposefully dumped in the past. When TCE enters the environment, its stability depends upon the situation. It evaporates easily and is significantly broken down in air within one week, possibly to phosgene, a lung irritant. Under high heat, it breaks down to phosgene and dichloroacetylene. In the human body, TCE may break down to dichloroacetic acid (DCA) and trichloroacetic acid (TCA), both of which are toxic to animals and possibly humans. TCE degrades in surface waters in days to weeks. The real problem with TCE occurs in the subsurface. It cannot readily evaporate from groundwater because of the lack of air and, therefore, breaks down very slowly. TCE is even more stable in soil, so it can persist almost indefinitely. From soil, it can be washed into groundwater during rain or thaw. TCE cannot be removed from water by most conventional methods used in wastewater treatment. The most common method is pump and treat using air stripping or activated charcoal. Bioremediation using certain genetically altered bacteria has also proven effective.

### HEALTH EFFECTS FROM EXPOSURE

TCE produces a variety of physiological effects when inhaled and with long exposure to the skin, especially if the skin is broken. It primarily depresses the central nervous system as do other anesthetics and produces symptoms similar to those of alcohol intoxication. Symptoms begin with headache and dizziness, progressing to confusion and then unconsciousness. These symptoms of short-term exposure dissipate after a few hours, although they may last longer if combined with alcohol. If exposure is too great, the respiratory and circulatory depression that results can be fatal. Cardiac sensitization to certain drugs can result in dangerous arrhythmias with TCE exposure as well. Frequent, repeated exposure to TCE can lead to long-term or permanent damage to the central nervous system. Symptoms include sleeplessness, fatigue, anxiety, irritability, personality disorders, and, later, poor coordination, difficulty in thinking, and loss of short-term memory.

TCE also causes minor to moderate irritation. As a degreaser, TCE strips the skin of its natural protective oils. With frequent exposure, skin can

be irritated, resulting in dermatitis and even burns and blistering in extreme cases. The vapor of TCE can irritate the eyes, nose, and throat. TCE can also damage the facial nerves and impair vision, smell, taste, and, in extreme cases, hearing and facial muscle control. There are reports of damage to the nerves of the arms and legs that caused loss of feeling, tingling, and even paralysis. At high levels and repeated exposures, TCE can produce severe damage. The lungs are irritated under these conditions, causing chest pain, shortness of breath, and possibly even pulmonary edema (fluid in the lungs), which can be fatal. In some cases, the heart of the victim has gone into fibrillation, which can lead to death. Liver and kidney damage has been reported, but only rarely, at very high concentrations. There is also evidence of immune deficiency disorders caused by TCE, but these are rare and the link is uncertain.

The connection of TCE to cancer and reproductive problems is also uncertain. It has been found to cause tumors in the liver, kidney, lungs, and testes in laboratory mice and rats at high dosage. Evidence of cancer in humans is more circumstantial. Studies in New Jersey and Massachusetts suggested a link between TCE in drinking water and leukemia in women and children, respectively. Another long-term study, in Michigan, Illinois, and Indiana, found no appreciable difference in incidence of cancer with environmental TCE exposure, except for a slight increase in lung cancer among older men. The study concluded that this increase was probably the result of increased smoking rather than TCE exposure. In contrast, several studies suggest that TCE in drinking water may cause birth defects in humans. One study found an increase in heart defects in babies whose mothers ingested TCE in drinking water. This study is supported by similar findings for animals in laboratory studies. Another study found an increase in a rare respiratory defect, as well as eye defects. Other birth defects attributed to TCE exposure include neural tube defects, oral cleft palates, hearing and speech impairment, and even childhood leukemia. Most of the results of the epidemiological studies yield only slight indications of a link between environmental TCE and these defects, which might be explained by other exposures that were not tested.

### REGULATIONS ON HUMAN EXPOSURE

As a result of these numerous and serious health effects from exposure to TCE, federal agencies regulate public and worker exposure. This regulation of TCE began in 1980 because it is covered under the Clean Water Act as a hazardous substance. In 1989,

the EPA set a drinking water standard for community water supplies of five parts per billion (ppb) of TCE. They also require industry to report any spill of 1,000 pounds (454 kg) or more. There is a proposal to reduce that number to 100 pounds (45.5 kg). The Occupational Safety and Health Administration (OSHA) set a national occupational exposure limit of 100 parts per million (ppm) in air for an eight-hour-day 40-hour workweek, although local jurisdictions may set their own standards. In California, for example, the limit is 25 ppm, and in Illinois it is 50 ppm. The national OSHA 15-minute maximal average is 300 ppm.

**temperature inversion** Normally, temperature decreases progressively with elevation above the Earth's surface. In some special cases, however, temperature may increase with elevation for a short distance above the surface before returning to the normal gradient. This special situation is a temperature inversion, and it commonly results in a period of increased to excessive air pollution. This situation has been responsible for virtually all the air pollution disasters. A radiation inversion type of temperature inversion occurs in very stable weather conditions

with no wind or precipitation. The Sun heats the Earth's surface by day; it, in turn heats the air above it. This is especially true in heat islands of cities with all of the blacktop pavement and brick, cement, and glass buildings. The heated air can extend quite high with the lack of wind. At night, the city cools, but air is such a good thermal insulator that it remains warm. Eventually, because the surface is cool, the air near the cooled surface cools to a lower temperature, thus making it denser and holding the pollutants near the ground. Topography can increase this effect when cold air flows down hills and concentrates in valleys. In either case, these radiation inversions last on the order of hours before the Sun heats the surface enough to reestablish a normal thermal gradient.

The much worse case is the subsidence inversion. This is a regular occurrence in cities that lie in valleys or basins and are prone to large high-pressure systems. One of the worst areas for this is Los Angeles, California. The Pacific high is a semipermanent atmospheric feature off the coast of California. In addition to the falling air from the high pressure, cool marine air from the Pacific Ocean significantly

cools the air at lower elevations, causing a substantial inversion. Further, the San Gabriel Mountains to the east inhibit the drifting of the weather system out of the Los Angeles basin commonly for an extended period (days to weeks). About 80 percent of the time between June and August, Los Angeles is smoggy and in a temperature inversion. Denver, Colorado, has a similarly unfortunate mix of topography, making it extremely susceptible to smog as well.

The high pressure forces air downward into a valley or basin, which prevents the air from escaping laterally. This causes the air to stagnate in the topographic enclosure. Normally, the common air pollution generated in an area is dispersed by dilution with circulating air. There is no buildup of these pollutants, and, as a result, few health problems under normal conditions. If the air cannot circulate because of a temperature inversion, pollutants quickly build to dangerous levels. If the weather does not break, an air pollution disaster can occur.

All the major air pollution disasters involving common air pollutants resulted from major and prolonged temperature inversions. The deadliest air pol-

Early morning steam from a midwinter temperature inversion shrouds the Aerial Lift Bridge in Duluth, Minnesota, 2005. (AP Images)

**Illustrated graph of temperature versus altitude during a temperature inversion. Normally, temperature would show a steady decrease with altitude. The inversion layer shows a reverse in this trend, and consequently exhaust gas is trapped beneath it, resulting in dangerous air pollutant levels.**

lution disaster was in London, United Kingdom, in 1952. A temperature inversion sealed smoke, automobile exhaust, and lesser amounts of industrial emissions in the city and up to 12,000 people died of respiratory failure as a result. The major American air pollution disaster was also caused by a temperature inversion, in Donora, Pennsylvania, in 1948. Cliffs along a river prevented lateral air movement, and largely industrial emissions concentrated to deadly levels. The other two major disasters involved temperature inversions that helped to build up deadly levels of sulfur dioxide gas from industrial sources. The first was in the Meuse Valley, Belgium, in 1930, and the second was in Poza Rica, Mexico, in 1950. Both resulted in death and both sparked changes in regulations of pollutants.

**Three Mile Island Middletown, Pennsylvania (March 28, 1979) Air Pollution** The accident at the Three Mile Island Unit 2 nuclear power plant was the most serious in United States nuclear power plant history. Even though it led to no deaths or injuries, the specter of a nuclear disaster at a commercial power plant captured the attention of the nation. Americans had long been warned of the dangers of nuclear power, and this situation had all of the signs of just such a disaster. As a result, the television and film industries picked up on the theme and "message" films, such as *The China Syndrome*, were released to critical and public acclaim and controversy. The incident and concern led to sweeping changes in emergency response planning, reactor operator training, radiation protection, and many other areas of nuclear power plant operations. It also caused the U.S. Nuclear Regulatory Commission to tighten its regulatory oversight on nuclear power plants. These changes in the nuclear power industry enhanced the safety and may prevent much more serious situations and potential disasters in the future.

#### THE REACTOR ACCIDENT

At 4:00 A.M. on March 28, 1979, Unit 2 of the Three Mile Island power plant had a malfunction in the secondary, nonnuclear section of the plant. The main cooling water pumps stopped running, preventing the steam generators from removing heat. As a result, the turbine and the reactor automatically shut down, and pressure began to increase in the primary nuclear section of the plant. The pilot-operated relief valve opened in order to prevent that pressure from becoming excessive. The valve was supposed to close when the pressure decreased to a designated level, but it did not. The signals that were meant to notify the operator that the valve was still open failed to operate. As a result, cooling water poured out of the stuck-open valve and caused the core of the reactor to overheat.

The information on the instruments of the reactor operators was confusing as more coolant flowed from the core through the pressurizer. None of them

showed the level of coolant in the core. The operators used the level in the pressurizer to determine the level of water in the core. They assumed that the core was properly covered with coolant because it was high. In addition, there was no signal showing that the pilot-operated relief valve was open. As a result, even though alarms sounded and warning lights flashed, the operators did not realize that the plant had lost coolant. Consequently, they reduced the flow of coolant through the core and made conditions worse. Without enough coolant, the nuclear fuel overheated to the point at which the long metal zirconium cladding tubes that hold the nuclear fuel pellets ruptured, and the fuel pellets began to melt. About one-half of the core melted during the early stages of the accident. Although Unit 2 suffered a severe core meltdown, the most dangerous kind of nuclear power accident, it did not proceed to a worst-case scenario. In this worst-case accident, the melting of nuclear fuel would lead to a breach of the walls of the containment building and release massive quantities of radiation to the environment.

## RESPONSE TO THE ACCIDENT

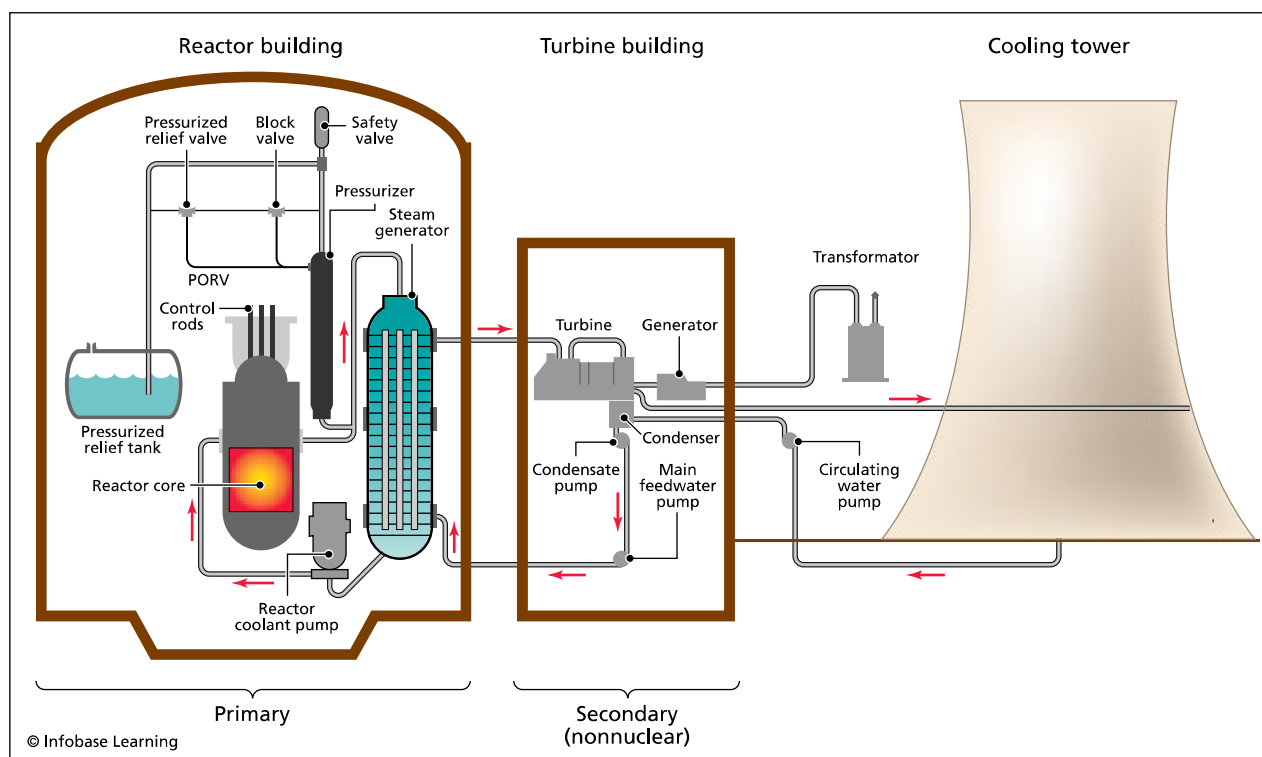

The U.S. Nuclear Regulatory Commission (NRC) regional office in King of Prussia, Pennsylvania, was notified of the accident at Three Mile Island at 7:45 A.M., three and three-quarters hours later. By 8:00 A.M., NRC Headquarters in Washington, D.C., was alerted and the Operations Center in Bethesda, Maryland, was activated. The first team of NRC inspectors was immediately dispatched to the site, and the U.S. Department of Energy and the U.S. Environmental Protection Agency (EPA) also dispatched their response teams. By midday, helicopters were sampling radioactivity in the atmosphere above the plant, and a team from the Brookhaven National Laboratory was sent to assist in radiation monitoring. By 9:15 A.M. the White House was notified, and by 11:00 A.M., all nonessential personnel were ordered to evacuate the plant.

The response teams appeared to have the plant stabilized by the evening of March 28 and whole day of March 29. On Friday, March 30, however, new concerns arose as there was a significant release of radiation from the plant auxiliary building during a pressure release on the primary system to avoid hampering the flow of coolant to the core. The growing uncertainty about the condition of the plant led Richard L. Thornburgh, the governor of Pennsylvania, to evacuate the nearby residents most vulnerable to radiation from the area. These vulnerable residents included pregnant women and preschool-age children within a five-mile radius of the plant.

Later, a large hydrogen bubble formed in the dome of the pressure vessel, the container that holds the reactor core. The fear was that the hydrogen bubble could explode and rupture the pressure vessel. If that happened, the core might fall into the containment building and cause a breach of the containment. This latest crisis ended when on Sunday, April 1, it was determined that the bubble could not burn or explode because there was no oxygen in the pressure vessel. By that time, they had succeeded in greatly reducing the size of the bubble.

## HEALTH EFFECTS OF EXPOSURE

Because this was the most serious accident that ever occurred at a U.S. commercial nuclear reactor, there were many detailed radiological studies conducted on the residents of the area by the NRC, the EPA, the Department of Health and Human Services, the Department of Energy, and the state of Pennsylvania, among others. Thousands of samples of air, water, milk, vegetation, soil, and foodstuffs were collected by numerous groups monitoring the area. Only very low levels of radionuclides could even be

**Diagram showing the components of the Three Mile Island Unit 2 nuclear reactor in which the accident occurred. Basically, the nuclear reaction in the core heats water into steam in the primary, which drives a turbine and generator in the secondary. The cooling tower prevents the reactor from overheating.**

possibly attributed to releases from the accident. Estimates are that the average dose to about 2 million people in the area was only about 1 millirem, about one-sixth the exposure from a full set of chest X-rays. Comprehensive investigations by several well-respected organizations concluded that in spite of the serious damage to the reactor, most of the radiation was contained and the actual release had negligible effects on the physical health of individuals or the environment.

### REGULATORY IMPACT OF THE ACCIDENT

The accident at Three Mile Island was caused by personnel error, design deficiencies, and component failures. It permanently changed the nuclear industry. Public fear and distrust of nuclear energy increased, the NRC's regulations became more stringent and oversight became broader, and the management of plants was more carefully scrutinized. The identification of problems that led to the accident has led to permanent and sweeping changes at the NRC that have reduced the risk to public health and safety.

The major changes include the upgrading and strengthening of plant design and equipment requirements such as fire protection, piping systems, auxiliary feedwater systems, containment build-

ing isolation, reliability of individual components including pressure relief valves and electrical circuit breakers, and ability of plants to shut down automatically. Other changes include the identification of human performance as a critical part of plant safety, revision of operator training and staffing requirements, improvement of instrumentation and controls for operating the plant, and establishment of fitness-for-duty programs for plant workers to guard against alcohol and drug abuse. There was an enhancement of the emergency preparedness system to include immediate notification of NRC for plant events and an operations center that is continuously staffed. Drills and response plans must be tested by licensees several times per year, and state and local agencies participate in drills with the Federal Emergency Management Agency.

Other changes include the issuing of annual public reports on the plants. There was enhancement of the inspection and the management systems including on-site offices. Expansion of performance and safety inspections, as well as the strengthening and reorganization of enforcement as a separate office within the NRC, were added. The Institute of Nuclear Power Operations (INPO) was established as the industry's own "policing" group. The Nuclear Energy Institute was formed to provide a unified approach to com-

mon nuclear regulatory issues and to interact with the NRC and other government agencies. In addition, the NRC's international activities were expanded to share enhanced knowledge of nuclear safety with other countries in a number of areas.

### CURRENT STATUS

The Three Mile Island reactor number 2 is now permanently shut down and defueled. The reactor coolant system is drained; the radioactive water is decontaminated and evaporated; the radioactive waste was shipped off-site to a disposal site; the reactor fuel and core debris have been shipped off-site to a Department of Energy facility; and the remainder of the site is being constantly monitored. It will be kept in the facility in long-term, monitored storage until the operating license for the Three Mile Island reactor number 1 plant expires, at which time both plants will be decommissioned.

After the Chernobyl disaster a decade later, Three Mile Island was largely forgotten because its effects and seriousness were dwarfed in comparison.

**tides** Tides are the periodic rise and fall of any liquids on or below the surface of the Earth. They are caused by response of the liquids to the gravity of the Moon and or Sun. Ocean tides are the most important and have the greatest influence on the environment. There are typically two high tides and two low tides per day separated by six hours each. High tides occur when the Moon is directly overhead or over the direct opposite side of the Earth. Low

tides occur when the Moon is one-quarter or three-quarters of the way around the Earth from the point of vantage. Therefore, if there is a high tide at 6 A.M., there will be a low tide at noon, another high tide at 6 P.M., and another low tide at midnight.

### TIDAL REACH

The tidal reach, or height, in an area at high tide and low tide varies throughout the month. This variability is caused by gravity imposed by the Sun. If the Sun, Moon, and Earth align (with the Sun on either side), high tides will be at their highest and low tides will be at their lowest. The reason for the extremes is that the gravities of the Sun and Moon are added. This situation is referred to as spring tide and typically corresponds to a full Moon. If the alignment of the Sun and Earth is positioned at a right angle to the alignment of the Moon and Earth, it is neap tide. Neap tides result in lower high tides and higher low tides than normal. Neap tides typically occur at half moon situations.

The main controlling factor in the tidal reach or height at a particular location is the shape of the basin. Smaller, shallower basins produce small tides and may even have only one tide per day. Lakes have small tidal reach. Larger, deeper basins generally produce larger tides. The shape of the basin and especially the margins also plays a big role in tidal reach. On the New Jersey shore, the typical tides are about six feet (1.85 m) high, whereas in the Bay of Fundy, Nova Scotia, Canada, the tides are an amazing 32 feet (9.85 m) high, yet both face the Atlantic Ocean. The difference is that the ocean floor is shallow and flat off the New Jersey shore but very steep and deep off Nova Scotia. There is more water available there to make larger tides.

### TIDES AND POLLUTION

Tides can have an influence on pollution in several ways. The primary effect of tides is on oil or chemical spills in the ocean. Tides can drive the oil and other pollutants up rivers and high onto beaches and shorelines, where it affects the terrestrial plants and animals. Waste disposed through ocean dumping can be pushed back onto beaches. High tides during storms can help to undermine and remove stored chemicals and other pollutants into the ocean, causing dangerous conditions.

The gravitational attraction of the Moon and, to a lesser extent, the Sun generates tides. The tidal range is largest (spring tides) when the Moon and Sun are in alignment relative to Earth. The tidal range is smallest (neap tides) when the Moon and Sun are at right angles.

### Times Beach Superfund site Times Beach, Missouri (1979–1997) Soil Pollution

Times Beach, Missouri, was a small (480-acre, or 194-ha) suburban community about 20 miles (32 km) west of Saint Louis. Built on the floodplain of the Meramec River, in the early 1970s, it had a population of approximately 1,200 people. Times Beach began as a 1930s vacation river town and had slowly evolved into a lower-middle-class community.

#### POLLUTION OF THE SITE

Every summer between 1972 and 1976, the city of Times Beach along with nearby businesses, farmers, and stables hired a local waste hauler to spray oil on unpaved roads for dust control. The cost of this spraying was \$0.06 per gallon (\$0.02 per L) of oil

applied. The waste hauler, Russell D. Bliss, picked up used or spent/off-spec oil from automobile service stations, heating oil distributors, machine shops, and other similar places, either free as a waste removal service or by paying a few pennies per gallon (3.8 L) for it. He then sprayed the oil on unpaved roads. The state of Missouri had licensed him as a waste hauler, and in the 1970s oiling was a common method of dust control.

Wishing to expand his small business, Mr. Bliss approached and was hired by Northeast Pharmaceutical and Chemical Company (NEPACCO) of Verona, Missouri, to dispose of spent chemicals from its agricultural chemical (a hexachlorophene-based pesticide) manufacturing operation. Instead, Mr. Bliss mixed these chemicals them with the used oil that he sprayed on the roads, horse tracks, and farms around the Times Beach area and some 26 other locations. Approximately 4,000–5,000 gallons (15,142–18,927 L) of oil containing 300 parts per million (ppm) dioxin was dispersed in this manner.

Dioxin, also known as 2,3,7,8-tetrachlorodibenzo-para-dioxin or TCDD, is the active ingredient in some types of pesticides and herbicides. During the 1970s, this compound was considered the most lethal substance ever created, 150,000 times more toxic than cyanide and 670,000 times as lethal as strychnine. It was the main component of Agent

Orange, a defoliant widely used during the Vietnam War. Subsequent studies indicate that dioxin compounds are no more dangerous than similar types of industrial and agricultural chemicals.

The first indications of potential environmental problems in Times Beach began in 1971. Local stable owners reported a sudden increase in the deaths of otherwise healthy horses. They found a common link: More than 60 horses had died in stables whose tracks, paddocks, and access roads had been oiled by Bliss. When confronted by the owners, Bliss assured them that the material he had used was simply motor oil and had nothing to do with the death of the animals. The stable owners were not convinced and contacted the Centers for Disease Prevention and Control (CDC). In late 1979, after an extensive investigation by CDC in addition to other state and federal agencies, a NEPACCO employee admitted that the company had been selling its waste dioxin to Bliss.

Concerned about the potential public health implications, the U.S. Environmental Protection Agency (EPA) began an investigation of Bliss's activities. In November 1982, the EPA notified Times Beach residents that the city might have been among the sites sprayed by Bliss with waste oil contaminated with dioxin. The EPA began collecting soil samples in Times Beach, even though the roads had since been paved and oiling was no longer needed to control the dust. One sample collected in early December 1982 contained dioxin levels almost 300 times greater than the concentration considered to be safe. As the sampling data were being reviewed and analyzed, heavy rains caused the worst flood in Times Beach history. The Meramec River crested 20 feet (6.2 m) above flood stage, and the flood spread dioxin-contaminated soil and mud everywhere. By the time the water started to subside, the EPA had confirmed the presence of dangerous levels of dioxin, and, on December 23, 1982, Times Beach residents received the following Christmas message from EPA officials:

If you are in town it is advisable for you to leave and if you are out of town, do not go back.

Sampling results confirmed the presence of dioxin at levels up to 100 parts per billion (ppb). The safe level was considered to be 1 ppb. Panic spread through the community and surrounding area, with many illnesses, miscarriages, and animal deaths attributed, correctly or not, to the dioxin.

The state police and national guard blockaded roads and refused to let anyone in or out. Dioxin, which is designed to cling tightly to soil particles, had been spread throughout the town by Meramec

River floodwaters. The now-contaminated soil covered the entire 0.8-square-mile (2.1-km<sup>2</sup>) area of Times Beach, and public health officials were concerned that if residents fled, they would track the contamination to other areas of Missouri.

### BUYOUT OF RESIDENTS

As the plight of the Times Beach residents attracted national attention, the federal government stepped in slowly to offer relief. In 1983, the EPA administrator, Anne Burford, announced a \$33 million buyout of the entire town of 437 permanent homes, 364 mobile homes, and 45 businesses. Residents rejected this compensation offer and a subsequent one by EPA because they were below market value. It was several years before the buyout was completed, but finally, after intervention by Missouri's congressional delegation, the EPA offered acceptable compensation. The stigma of having lived in Times Beach, however, was not as easy to overcome. Evacuees from Times Beach often were shunned by their new neighbors, who were afraid that the effects of dioxin exposure might be contagious.

Russell Bliss denied any wrongdoing, claiming that NEPACCO had never informed him that the material was hazardous. This conflicted with testimony by NEPACCO employees that Bliss's drivers were issued protective clothing and warned of the dangerous nature of the waste during pickups. Bliss's waste-hauling license was not renewed, and, despite his questionable disposal practices, he was never indicted or convicted of any crime. In 1983, Bliss and NEPACCO were sued by 183 of the town residents for \$1.8 billion in damages. NEPACCO declared bankruptcy the following year. Its insurers settled the lawsuit for \$19 million, with each plaintiff receiving, on average, slightly more than \$100,000, before attorney's fees.

### THE CLEANUP

The cleanup implemented by the EPA was unique and has never been repeated since on such a massive scale. Between March 1996 and June 1997, more than 10 years after the contamination was discovered, approximately 240,000 tons (217,724 metric tons) of soil and every building, structure, and part of the town (except for one small house) were burned in a high-temperature incinerator constructed near the former municipality. This debris included essentially all of Times Beach and most of the ground it rested on.

After collection and processing by shredding, grinding, and adding lime to reduce moisture levels,

the waste material was incinerated in a 75-foot- (23-m-) long rotary kiln lined with a nine-inch- (22.9-cm-) thick layer of high-temperature, acid-resistant insulating refractory. Processing about 40 tons (36.3 metric tons) of waste per hour, the kiln rotated at one rotation per minute (rpm) and reached a firing temperature of 1,250°F (677°C). At these temperatures, the chemical bonds holding the organic compounds together were destroyed, and the material was broken down to its basic elemental components (carbon, hydrogen, chlorine, etc.). Just to make sure all the dioxin was thoroughly destroyed, exhaust gases from the kiln were routed to a secondary combustion chamber that operated at an even higher temperature of 1,750°F (954°C).

The incinerator also was equipped with an emergency backup system. If the primary and secondary burners failed, gases from the kiln would be diverted to a propane-fired 1,800°F (982°C) backup furnace until the system could be shut down, the wastes secured, and the problem repaired. The permit for the burning of the Times Beach waste required a dioxin removal efficiency of 99.999 percent, which this system was able to achieve, and no public health effects were reported during its opera-

tion or after the incinerator was decommissioned and dismantled.

### THE AFTERMATH

The ash and other noncombusted residues were buried and covered with clean fill, and the area was redeveloped as Route 66 State Park. Times Beach is now one of the most visited tourist attractions in Missouri. Only one building from the town still stands, an old roadhouse that had been the EPA's headquarters during the cleanup but now serves as the park's visitor center. The cost of remediation to the federal government was approximately \$140 million, \$10 million of which was reimbursed by Syntex, NEPACCO's parent company.

Illnesses related to toxic exposures to dioxin affected 10 people. Most severely affected was a six-year-old who suffered kidney and bladder damage that required hospitalization and surgery. Less severely affected persons developed diarrhea, headaches, nausea, and skin lesions. Some 63 horses, six dogs, 12 cats, and 70 chickens died as a result of dioxin poisoning, along with uncountable rodents and insects. Later research on the toxicity of dioxin

Loading of dioxin-contaminated debris at Times Beach, Missouri, 1983 (© Bettmann/CORBIS)

has led to controversy as to whether the EPA's decision to evacuate and incinerate Times Beach was appropriate.

#### **Tittabawassee River contamination Midland, Michigan (2000–present) Soil and Sediment Pollution**

The Michigan Basin is a bowl-shaped structure of sedimentary rock located near the center of the Lower Peninsula of Michigan. The basin was actively subsiding during sedimentation as recorded by Early Paleozoic (500 to 400 million year old) rocks more than 15,000 feet (4.6 km) thick in the center, but 4,000 feet (1.2 km) thick around the margins. Overlying units show the same thickening toward the center. This active subsidence in an enclosed area of high temperatures also resulted in the deposition of a significant thickness of salt, gypsum, and other evaporate rocks for which the area has become renowned.

As Michigan's Lower Peninsula was explored and settled, first by trappers, then for its timber and later rich farmland, early pioneers discovered outcrops of salt and related deposits. Sometimes, these early explorers found mastodon and saber-tooth tiger bones, among others, near these deposits, the remains of prehistoric animals drawn there by the salt. Commercial developers exploited these salt deposits, and for many years in the early 1900s, Michigan was one of the major salt-producing states in the country.

#### BACKGROUND

A chemist named Herbert Henry Dow was also drawn to these deposits of salt and the brine-rich groundwater associated with them. In 1879, Dow began a company in the small town of Midland, Michigan, to test his new procedure for the extraction of bromine from the natural brines that could be pumped to the surface in parts of Midland, Manistee, Muskegon, Wayne, and Saint Clair Counties. Bromine was an important chemical at the time and was often found associated with salt deposits. It was used in fumigants, pesticides, dyes, and water purification and in film for the rapidly expanding photography industry. Bromine is a heavy, volatile, mobile, and very dangerous reddish brown liquid. Similar to chlorine and often used as a bleaching compound, it has a strong unpleasant odor, and bromine vapors can irritate the eyes and throat.

The Dow Corporation started to grow quickly, at first selling potassium bromide and bleach and eventually diversifying to become one of the major providers of plastics, chemicals, and agricultural products. Today, it is the world's second largest chemical manufacturer with operations in more than 150 countries and more than 45,000 employees. In 2009, Dow's annual sales totaled approximately \$50 billion. Despite its rise in commercial importance, Dow never abandoned its Michigan roots. The company still is headquartered in Midland and operates a 1,900-acre (769-ha) facility on the southern edge of town. Products produced by Dow at Midland include Saran Wrap, Styrofoam, Mustard Gas, Agent Orange, and various agricultural pesticides.

#### POLLUTION OF THE SITE

To manage its liquid wastewaters, in the early 1900s, Dow Chemical constructed a series of lagoons, or ponds, on a 600-acre (243-ha) parcel of its Midland plant. Wastewater was discharged into these ponds, solids allowed to settle, and decanted liquid discharged into the adjacent Tittabawassee River. Today, liquid wastes generated from production operations are processed through Dow's advanced wastewater treatment plant before being released into the environment.

The Tittabawassee River flows southward through the Lower Peninsula in the east-central portion of the Michigan Basin and eventually joins the Shiawassee River to form the Saginaw River near Midland, just downstream of the Dow plant. The Saginaw River then enters Saginaw Bay, which leads into Lake Huron. During high-flow periods, after heavy rains, for example, Dow intentionally released excess liquids from the waste ponds. Even though

**Discharges of dioxin-contaminated wastewater from this chemical plant significantly impact sediment quality in the adjacent Tittabawassee River, Saginaw, Michigan, 2005. (Junebug Clark/Photo Researchers, Inc.)**

this was a standard waste management practice at the time, these and other types of wastewater discharges had a significant impact on the environment. In particular, a flood in 1986 overwhelmed the Dow treatment plant, submerged portions of the manufacturing area, overflowed containment dikes, and washed untreated chemical wastes and contaminated soil into the Tittabawassee River. When it finally subsided, a 20-mile (32-km) stretch of river downstream of Dow's Midland facility was contaminated with dioxins and furans.

Dioxins and furans are a class of related chemicals that are more correctly known as polychlorinated dibenzo-para-dioxins and polychlorinated dibenzofurans and contain 210 individual compounds (75 dioxins and 135 furans). Dioxins and furans are not manufactured intentionally; they are by-products of several commercial chemical processes. Scientific studies show that short-term exposure to elevated

levels of dioxins and furans results in a wide variety of health problems such as skin disorders (chlor-acne), liver damage, immune system damage, and the development of certain types of cancers. Almost all environmental and public health agencies worldwide have established very low exposure guidelines for these substances, especially for 2,3,7,8-tetrachloro-p-dibenzo-dioxin (2,3,7,8-TCDD), which generally is acknowledged to be the most toxic of the dioxins and furans. Once in the environment, dioxins and furans are very resistant to biodegradation and move up the food web, becoming concentrated in body fat. The vast majority of an individual's exposure to dioxins and furans is through meat, milk products, and fish.

Dioxins and furans were discovered in the channel and floodplain sediments of the Tittabawassee River in 2000 during an ecological sampling program being conducted downstream of the Dow plant in Midland by General Motors Corporation. During a wetland restoration project, General Motors sampled and analyzed sediments in a farm field in the Tittabawassee River floodplain adjacent to one of their manufacturing facilities and discovered dioxins and furans at concentrations up to 2,200 parts per thousand (ppt), about 25 times higher than allowed by state regulations. General Motors promptly notified the Michigan Department of Environmental Quality (MIDEQ), which initiated an investigation. Early studies by MIDEQ found that dioxin and furan levels in sediment samples increased nearer to the Dow plant but decreased dramatically upstream of the facility to less than 10 ppt. Soil samples taken from outside the floodplain contained concentrations of dioxins and furans at background levels of about 6 ppt.

Levels of dioxin downstream of the Dow plant ranged from 39 ppt to more than 7,200 ppt in channel and floodplain sediments. Michigan's current residential cleanup standard for dioxin is 90 ppt, whereas the federal Agency for Toxic Substances and Disease Registry (ATSDR) has an action level of 1,000 ppt (or one part per million [ppm]). Other states have different cleanup criteria for dioxin: in Oregon, Washington, West Virginia, Massachusetts, and Florida, less than 10 ppt; in Iowa and Arizona, 14 ppt and 38 ppt, respectively; in Pennsylvania, 120 ppt; and in Minnesota, 200 ppt.

### THE CLEANUP

In compliance with Michigan law, which requires all who release a hazardous substance onto their own or another's property to take corrective action, Dow is implementing a variety of remedial actions to address the dioxins and furans from its facility in Midland. Dow identified and mapped areas where

dioxin is present at levels above 90 ppt. These maps play a critical role in the development and implementation of a comprehensive long-term plan to address the dioxin-contaminated sediments and soils in the channels and floodplains of the Tittabawassee River.

Dow Chemical is also working cooperatively with MIDEQ and local health officials to educate residents on ways to reduce exposure to dioxin. For example, animals that graze on plants grown in dioxin- or furan-contaminated soil ingest these compounds and retain them. The dioxins and furans can then be passed on to people who consume the meat, milk, or eggs of these animals. Health advisories have been issued for eating fish from the Tittabawassee River downstream of Midland. Bottom feeders that tend to feed in sediment such as carp, catfish, or white bass should not be eaten, and children and pregnant women should not eat any fish from the river more than once per month. Similarly, Midland County health officials are urging residents to avoid eating animals that have grazed in floodplain sediments downstream of the Dow plant and have advised landowners not to conduct activities that may disturb floodplain sediments such as dredging or regrading.

Finally, Dow has implemented short-term remedial measures to reduce the risks to children or those who have impaired immune systems because they have the greatest potential for sensitivity to dioxin. In those cases, contaminated soil has been excavated from backyards. This phased approach to cleanup has been slow, and some government officials, community leaders, and local environmental activists are unhappy with the delays. In 2005, some 2,000 property owners within the floodplain of the Tittabawassee River filed a class action suit against Dow for diminution of property values, claiming that their land is now essentially worthless because of the dioxin contamination. Dow successfully fought to prevent the class action from being certified, claiming that the plaintiffs' cases were different, and should be tried on a case-by-case basis. The landowners are now appealing that decision, and the suit is working its way through the court system as both Dow and MIDEQ continue to search for a way to address this area of widespread contamination.

**tobacco smoke** Tobacco is, by far, the deadliest environmental hazard in the world, directly causing more than 420,000 deaths (one in five) in the United States per year alone. It has been called "the leading preventable cause of disease and death in the United States" by the surgeon general. There are more tobacco-related deaths per year than deaths from human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), illegal drug use, alcohol use, motor vehicle accidents, suicides, and murders combined. There are three sources of tobacco exposure, smoking, smokeless (chewing and snuff), and environmental tobacco smoke. By far, the most deadly is smoking, but it is more a health than an environmental issue. There will be a short review of effects directly related to smoking and smokeless tobacco, but the main point of this discussion is environmental tobacco smoke, or secondhand smoke. In recent years, the adverse health effects of secondhand smoke have raised as much concern as direct smoking. Many states and municipalities have passed laws regulating exposure in most public buildings, even in businesses traditionally known for smoking, from restaurants to bars and night clubs. The public outcry against smoking has reduced its use and consequently public exposure, and this trend is likely to continue into the future.

#### HISTORY, USE, AND PRODUCTION

Tobacco is an American product. There is Mayan art depicting its use as much as 1,500 years ago.

**Tobacco smoke contributes to indoor air pollution and poses serious health risks to nonsmokers, especially children.**  
(Manuel Martinez; used under license from Shutterstock, Inc.)

European explorers in the 1500s were the first non-native Americans to use tobacco. Its use spread from the Americas to Europe in the middle of the 16th century, and from there, it spread throughout the world. The most popular form of tobacco use was as snuff, prior to the 1800s, in both Europe and the United States. Chewing tobacco use increased until it peaked in 1900 at 4.1 pounds (1.9 kg) per American male older than the age of 15. Cigars and pipe tobacco were the most popular forms of smoking in the 18th and 19th centuries. They were rapidly replaced by cigarettes after about 1910. The annual per capita use of cigarettes in 1900 was about 54 for Americans. By 1963, it had reached 4,345, when it peaked. The consumption of cigarettes steadily declined thereafter, largely through education of the general public about the emerging research that showed how deadly tobacco is. By 2002, annual per capita consumption of cigarettes had dropped to fewer than 2,000. In terms of total cigarettes, the consumption was 2.5 billion in 1900, 640 billion in 1981, and 420 billion in 2002. There was a small resultant shift toward chewing tobacco as consumption of cigarettes declined. In 1962, the consumption was 0.5 pound (0.23 kg) per year but

increased to 1.05 pounds (0.48 kg) per year by 1966 and 1.34 pounds (0.61 kg) per year by 1982 before declining to 0.8 pound (0.36 kg) per year, where it has remained, by 1991.

Tobacco has been produced as a major economic crop in the United States since the 1600s. Between 1987 and 1997, the tobacco harvest in the United States was approximately 1.19–1.79 billion pounds (540–812 million kg) per year. Imports totaled 11 billion cigarettes in 2000 but more than 20 billion by 2002. Exports of tobacco greatly outnumber imports with 148 billion exported in 2000 and 127 billion in 2002.

### TYPES AND COMPONENTS OF TOBACCO SMOKE

Tobacco smoke of all kinds is a complex mixture of a vast array of chemical compounds. To date, approximately 4,000 chemical compounds have been identified of the estimated 100,000 total in tobacco smoke. These 4,000, however, represent 95 percent of the total mass. Included in these 4,000 compounds are more than 50 that are known carcinogens and up to 400 that are toxic. These numbers depend upon the fertilizer used in tobacco growth, the chemicals used in processing, pH, and the method of smoking, among other things. One source of the hazardous substances is the burning or partial burning of the tobacco and paper. The other main source is the tobacco itself, which has been used in phytoremediation because of its ability to uptake dangerous substances during growth. A much less important source are the up to 600 additives that are included in tobacco during processing. Among the hazardous compounds in tobacco smoke are tar, arsenic, lead, cadmium, nickel, carbon monoxide, carbon dioxide, nitrogen oxides, hydrogen cyanide, benzene, ethylbenzene, vinyl chloride, dioxin, polycyclic aromatic hydrocarbons (PAHs) including benzopyrene, volatile and nonvolatile aldehydes and ketones, hydrazine, quinones, butadiene, radioactive polonium, ammonia, N- and other nitrosamines, phenols, alcohol, carboxylic acid, formaldehyde, nicotine, sulfur dioxide, and various pesticides and fertilizers. With an ingredient list like this, it is no wonder that tobacco smoke is dangerous.

There are two basic modes of smoke exposure, direct inhalation and environmental tobacco smoke, which is also known as passive smoking and secondhand smoke. Of these, there are two kinds of smoke, mainstream, which is drawn through the tobacco column and directly into the respiratory system, and sidestream, which is produced by smoldering. This difference is not just in delivery method. Mainstream smoke is produced at higher tempera-

tures (1,650°F [900°C]) and under pressure flow at high oxygen conditions. It is primarily composed of nitrogen oxides and other compounds (58 percent), carbon dioxide (13 percent), oxygen (12 percent), carbon monoxide (3.5 percent), hydrogen (0.5 percent), particulate matter (8 percent), and all other elements and compounds (5 percent). Sidestream smoke is produced at lower temperatures (1,022°F [600°C]) with no flow and under oxygen-deficient conditions. Sidestream smoke results in incomplete burning of tobacco, which produces carbon monoxide as well as 40–170 times the ammonia content of mainstream smoke, four to 10 times the content of nitrogen oxides, 10 times the benzene content, six to 100 times the N- and other nitrosamines, and 30 times the aniline. The higher flow also reduces the size of particulate from 0.1 to 1 micrometer for sidestream smoke to 0.01–0.1 micrometer for mainstream smoke.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous devastatingly adverse health effects from exposure to tobacco smoke and its by-products. In short, humans were not designed to inhale burned and partially burned substances for any length of time. Except for nicotine poisoning for very high doses, most effects of exposure to tobacco smoke are minor and in the form of irritation of the eyes and upper respiratory system. It is the long-term effects from chronic exposure that are particularly devastating and fall into categories of cancer, repro-

ductive problems, pulmonary disease, respiratory disease, and miscellaneous effects. The EPA, World Health Organization, and International Agency for Research on Cancer all consider both direct and secondhand smoke known human carcinogens. Cigarette smoking is responsible for 87 percent of all lung cancer deaths and 30 percent of all cancer deaths in the United States. Lung cancer is the leading cause of death of all cancers at about 119,920 per year, and smoking increases the chance of contracting it by 22 times for men and 12 times for women. In addition to lung cancer, smoking has been shown to increase the likelihood of cancers of the larynx, oral cavity, nasal cavity, sinuses, pharynx, esophagus, urinary bladder, renal pelvis, kidneys, pancreas, uterine cervix, and stomach, as well as increasing the incidence of acute myeloid leukemia. Total deaths per year from these cancers are about 31,402. These epidemiological findings for humans are supported by studies on laboratory animals. Laboratory studies also show that tobacco smoke causes genetic mutations in most cell types, especially as the result of exposure to N-nitrosamines.

Damage to the pulmonary system from tobacco smoke and especially cigarette smoke is also a major health threat. Atherosclerosis is the buildup of fat on the artery walls, is greatly increased by smoking, and is one of the major contributors to the high number of deaths. The risk of dying from the pulmonary effects is three times as high in smokers (about 30 percent of those in the United States) and is estimated at 134,235 per year. The artery dam-

**Histogram showing the loss of life expectancy for several life-threatening hazards. Smoking one pack of cigarettes daily is by far the most devastating of all hazards, on average reducing lifespan by 2,370 days, or 6.5 years, whereas smoking more than one pack daily reduces it proportionally more.**

age results in coronary heart disease, which leads to heart attacks. Smoking also increases the likelihood of recurrent coronary heart disease after bypass surgery. It reduces the amount of high-density lipoprotein (HDL), or good, cholesterol in the blood system and generally increases blood pressure. These further the likelihood of heart attack as well as blood clots, stroke, peripheral arterial disease (incidence increased 10-fold), and abdominal aortic aneurysm. Oral contraceptives work synergistically with smoking to promote strokes, which are more likely in women, in general, thus exacerbating an already dangerous situation. Smoking-induced strokes are twice as common as those in nonsmokers and kill an average of 23,281 people per year. The greatest killer from secondhand smoke is coronary heart disease by far.

Tobacco smoke also causes a variety of other diseases including bronchitis and emphysema, which are increased 10-fold and kill an average of 14,865 people per year; asthma and chronic airway obstruction, which kill 48,982 people per year; pneumonia resulting in about 19,173 deaths per year; burn deaths at 1,362 deaths per year; damaged immune system, reduced bone density, and cataracts. Smoking also increases infertility and may increase the likelihood of preterm delivery, stillbirths, low birth weight, and sudden infant death syndrome (SIDS) if the mother smokes.

Nicotine is the highly addictive drug in tobacco smoke that keeps people smoking. It is considered to be on the same level of addictiveness as heroin and cocaine and has similar effects on the brain. Nicotine acts synergistically with those drugs to keep hard-core addicts using. The rate of cigarette smoking among drug addicts is much higher than among the general public, and nicotine is considered a “gateway drug” for these and other hard-core drugs. In small doses, nicotine acts as a stimulant to the brain, but in large doses, it is a depressant that disrupts nerve transmission. It is for this reason that smoking may cause depression. To be fair, however, it is suggested that this interference may also reduce the risk of Parkinson’s disease, ulcerative colitis, Kaposi’s sarcoma, and Alzheimer’s disease and relieve the symptoms of Tourette syndrome. At high dosage, nicotine is a deadly poison that damages the heart and blood vessels as well as altering hormone levels. At high exposures, it can be fatal.

A 50-year study on smoking effects on male physicians in the United Kingdom shows that the real culprits in the dangers of tobacco smoke are cigarettes. The study showed that on average, lifetime smokers lose 10 years of life expectancy. A smoker who quits by the age of 30 suffers no long-term

effects, but by age 60, he or she has lost 7 of the 10 years. Even more important, smokers born in the late 19th century, when cigarettes were rare, had a 12 percent death rate versus a 10 percent death rate for nonsmokers. In contrast, death rates for smokers radically increased when cigarettes became popular in the 1920s. The death rate in the 1990s was 33 percent for lifetime smokers versus 7 percent for nonsmokers.

Environmental tobacco smoke (ETS) is one-tenth as deadly as direct smoking, but even at that level, it kills at least 38,000 people per year, making it the most dangerous documented environmental substance to humans. ETS produces many of the same health effects as direct smoking but in lower and different proportions. The most prevalent adverse health effect from ETS is ischemic heart disease. Its incidence is doubled among people who are regularly exposed to ETS, and it kills an estimated 35,000 people per year. It is also estimated to be responsible for 3,000 lung cancer deaths per year. Children are exposed to ETS if their parents smoke, a very dangerous condition. It may be responsible for as many as 300,000 lower respiratory tract infections per year in children below the age of 18 months. In a new epidemiological study, ETS has been shown to increase the incidence of cancer in the nasal sinus, but the rate and additional deaths are unknown. Smoke condensate, the yellow stain on walls and other areas, has been shown to cause skin tumors in mice, adding another potential problem. The health effects of ETS may be increased as time goes on as it is much more recently designated as carcinogenic and less studied.

### HUMAN EXPOSURE TO SMOKE

For direct smoke, only the smoker is affected, but for ETS, many people are affected. ETS is largely an indoor air pollutant, in too low quantity and dispersing too quickly to be of danger as an atmospheric air pollutant. The Centers for Disease Control and Prevention in their third National Health and Nutrition Examination Survey conducted from 1988 to 1991 estimated that 90 percent of the U.S. population of four years or older had detectable levels of a marker chemical, cotinine, produced by ETS in their blood. One positive sign is that the average level of cotinine was found to be reduced fourfold between 1991 and 1999. In 1991, some 43 percent of children between the ages of two months and 11 years lived in a home with at least one smoker. Even by 2001, approximately 9 million to 12 million American children six years old or younger were exposed to tobacco smoke in their

homes. Before restrictions were in place, certain businesses had higher exposures to ETS than others. The exposure in restaurants was 1.6–2.0 times as high as in the workplace and 1.5 times as high as in the average home. The exposure in bars was 3.9–6.1 times as high as in the workplace and 4.4–4.5 times the average levels in residential settings. These exposures are especially worrisome for people who work in these businesses because their total exposure is much higher.

### REGULATIONS ON HUMAN EXPOSURE

The number of regulations has accelerated in recent years in some parts of the country but lags in others. On the federal level, all federal buildings must be completely smoke-free whether owned or leased, and outdoor smoking areas must be restricted to ensure that no smoke will enter air intake ducts as mandated by Executive Order 13058. Smoking is banned on all commercial airplanes that operate within the United States whether foreign owned or domestic. OSHA prohibits smoking around certain substances. Warnings for the adverse health effects of smoking must be clearly labeled on all products, and there are severe restrictions on advertisements for tobacco products. The most effective regulations, however, are the result of state and local legislation. All state offices are smoke-free, as are most businesses. Many sporting events and other entertainment venues are smoke-free. In many areas, restaurants are smoke-free and there is even legislation proposed to ban smoking in bars and casinos. The goal for the Centers for Disease Control and Prevention is to reduce cigarette smoking to 12 percent and ETS exposure to 45 percent for nonsmokers and 10 percent for children by 2010.

**toluene** Toluene is one of the most common chemical compounds and widespread environmental pollutants, but paradoxically comparatively very little is produced relative to that which is used and enters the environment. The reason for this paradox is that it is a natural component of crude oil and gasoline and never recovered but simply burned in gasoline engines and other combustion devices. It is the *T* in the ubiquitous and necessary BTEX (benzene, toluene, ethylbenzene, xylene) component of fuel. This "contained" toluene amounts to well more than 1 billion pounds (454 million kg) used per year. It also occurs naturally in the tolu tree, for which it is named. Toluene is a volatile organic compound (VOC) that also has anthropogenic sources and numerous applications in everyday life as well as industry. It was identified as a pollutant, however, in 851 of the first 1,350 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) where it was tested, making it one of the most common and widespread pollutants in the world. Its adverse health effects and widespread distribution make it a concern. As a result, it was ranked as the 71st most hazardous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

### PRODUCTION AND USE

Pure toluene is a clear, colorless liquid with a strong smell that evaporates quickly. It is primarily produced to make benzene, accounting for 50 percent of all use in 1992. Other uses include gasoline blending to increase octane (30 percent), to produce toluene diisocyanate (7 percent), as miscellaneous chemicals (7 percent), and as solvents and in solvent extraction (6 percent). As a solvent, it is used in both industrial and consumer applications in aerosol spray paints,

wall paints, lacquers, inks, adhesives, natural gums, resins, spot removers, paint strippers, cosmetics, perfumes, and antifreeze. Of that which is turned into toluene diisocyanate, 90 percent is used to produce polyurethane foam. Flexible foam is used primarily in furniture (43 percent) and bedding (12 percent). Rigid foam (35 percent) is used primarily in insulation in housing and in appliances. The remaining 10 percent of toluene diisocyanate is used in floor finishes, wood finishes, paints, sealants, coatings, adhesives, and some plastic parts. The production capacity of the United States for toluene is nearly 2 billion gallons (7.56 billion L) per year, and yet only 800 million gallons (3.02 billion L) was produced in 1991. That year, some 62 million gallons (234.4 million L) was imported and 52 million gallons (197 million L) exported. Expected growth in production is estimated at 3 percent per year. Toluene diisocyanates are available in two isomers (2–4, 85 percent, and 2–6, 15 percent) and have been commercially available since the 1930s. Production in the United States increased from 616 million pounds (280 million kg) in 1985 to 869 million pounds (395 million kg) by 1995. At the same time, imports declined from 29 million pounds (13.2 million kg) in 1985 to 155,000 pounds (70,455 kg) in 2000 while exports increased from 9 million pounds (4.09 million kg) to more than 503 million pounds (228.6 million kg) during the same period. Toluene diisocyanates have similar properties to toluene's, but they can be crystalline solids, and they can be explosive when mixed with certain chemicals.

### ENVIRONMENTAL RELEASE AND FATE

Toluene is released into the environment through several pathways. Leaking storage tanks, illegal handling and dumping, and spills during transfer and transport are common ways it may be released to soil and surface water as a point source pollutant. It is a significant component of gasoline and is released during gasoline and other fuel releases, as well as refining operations. In this way, it can also be a nonpoint source pollutant. If soil is contaminated, toluene primarily evaporates or leaches into groundwater. If the soil is rich in organics, however, up to 97 percent of the infiltration toluene is adsorbed and becomes immobile. Within the soil, it is degraded by microorganisms, but it is slow to degrade at high concentrations because of its toxicity. It typically takes the microorganisms three to four days to become acclimated to the toluene in groundwater, and then it has been found to take as little as eight days to degrade it completely in some cases, but up to four weeks to degrade 2 percent of it in others. In shal-

low flowing surface water, toluene evaporates very quickly with an experimentally determined half-life of 2.9–5.7 hours. In another experiment with deep, still water and cold temperatures, the half-life was 13 days. Most toluene, however, is released into the atmosphere either directly or indirectly from soil and water. It is primarily released directly from evaporation of gasoline and other fuels, toluene-based solvents, motor vehicle exhausts, and emissions from fossil fuel-burning power plants and incinerators. In the atmosphere, it degrades rapidly through chemical reactions with photochemically produced pollutants or is washed out during precipitation. The half-life of this degradation under normal conditions is three hours to a little more than one day. In 1992, it is estimated that 193 million pounds (87.7 million kg) was released into the environment, 191 million pounds (86.8 million kg) of which (99 percent) was into the atmosphere, 84,000 pounds (38,180 kg) into surface water, 708,000 pounds (321,818 kg) into the land, and 1.6 million pounds (727,272 kg) into injection wells. Between 1987 and 1993, the top 10 states for environmental release of toluene in order were Texas and California by far, followed by Connecticut, Oklahoma, Virginia, Wisconsin, Illinois, Michigan, West Virginia, and South Carolina, primarily by petroleum refining and petroleum/coal products. Another major source of toluene exposure is cigarette smoke at about 80 micrograms per cigarette. Toluene diisocyanate is also primarily released to the air. Release is primarily through commercial handling, processing and production, emissions from industrial plants, and release from sprays, insulation, polyurethane foam, and coated fabric. The 1999 release of the two toluene diisocyanate isomers to the environment totaled nearly 112,000 pounds (50,900 kg).

### HEALTH EFFECTS FROM EXPOSURE

Exposure to toluene has been shown to produce several negative health effects. Acute inhalation exposure primarily affects the central nervous system. Low-dose exposure typically produces fatigue, confusion, loss of coordination, nausea, eye irritation, and impaired reaction time, as well as perception and motor control. High doses may result in narcosis and even death through respiratory failure. Long-term chronic exposure to toluene typically produces headaches, confusion and memory loss, tiredness, weakness, nausea, loss of appetite, loss of muscle control; problems with speech, vision, and/or hearing; decreased mental ability; and possible damage to kidneys. Toluene works synergistically with alcohol to damage the liver and with aspirin

and acetaminophen to damage the hearing. Most negative health effects on laboratory animals also involved the central nervous system. Long-term exposure to toluene also produced increased kidney, liver, lung, and heart weight in rats and mice, as well as necrosis of the brain and urinary bladder hemorrhage in rats. They also developed respiratory, hearing, and olfactory problems. Exposure of pregnant rats and mice to toluene resulted in damage to offspring, primarily in delayed skeletal development in rats and birth defects in mice. There are studies that suggest central nervous system abnormalities and developmental delays in humans. Toluene is classified by the EPA as group D: no clear indication that it is a human carcinogen. Toluene diisocyanate, however, is reasonably anticipated to be a human carcinogen. Experimental results of exposure in mice indicate cancerous conditions in the spleen, liver, ovaries, and other areas, whereas rats showed increased cancer development in the liver, pancreas, mammary glands, and related areas.

### REGULATIONS ON HUMAN EXPOSURE

There are several federal regulations regarding human exposure to toluene and toluene diisocyanate. The EPA has set a drinking water limit of one part per million (ppm) for toluene. They further recommend that a person not be exposed to more than 20 ppm for one day or 3 ppm for more than 10 days. Any release of more than 1,000 pounds (454 kg) of toluene to the environment must be reported to the National Response Center. Both the Occupational Safety and Health Administration (OSHA) and National Institute of Occupational Safety and Health (NIOSH) limit workplace air to less than 100 ppm over an eight-hour-day, 40-hour workweek. In contrast, spills of 100 pounds (45.5 kg) of toluene diisocyanate must be reported to the National Response Center. OSHA recommends a ceiling concentration of 0.02 ppm of the toluene 2,4-diisocyanate isomer, and NIOSH set a designation of immediately dangerous to life and health (IDLH) for a 2.5-ppm exposure to the toluene 2,4-diisocyanate isomer.

**tornado** A tornado is the most destructive type of storm on Earth by virtue of its ferocious winds. A tornado can appear suddenly and demolish whole towns within minutes. Fortunately, it is small in size (typically hundreds of feet across) and short-lived, and the more destructive varieties are regionally restricted. For these reasons, a hurricane, which is much larger and longer-lasting, is capable of much more extensive amounts of total damage. The threat to the environment from a tornado results completely from the structures and objects that it can destroy at the surface. Not only can it wreck habitats and kill animals and vegetation, but also it can rupture and destroy virtually any manufacturing, transportation, and storage structure for dangerous chemicals on the surface. It is in this way that a tornado is the greatest threat to people and the environment.

### FORMATION OF A TORNADO

A tornado forms from a thunderstorm under very specific conditions. A thunderstorm forms in hot, moist, and low-density air (rising) at the ground surface that is affected by cooler, denser air (sinking) aloft, thus producing unstable conditions because of the inverted density structure. These conditions involve vigorous vertical circulation of air to high levels in the troposphere as the air density attempts to equilibrate. The circulation of air occurs in convection cells that may be individual, or single-cell storms; multicellular storms; with many convection

cells; or supercell storms, if the circulation is large and intense. A tornado may form in multicell storms, but the supercell storm is by far the primary tornado producer.

The dominant direction of circulation in the storm determines its nature. A storm in which upward movement dominates draws warm moist air to higher, cooler levels and causes high amounts of condensation. This kind of storm is characterized

by heavy rain but not much wind. Other kinds of storms may be dominated by downward movement of air, which causes substantial straight-line winds and microbursts but little rain. The most intense storms are characterized by intense upward and downward movement of air. The upward movement causes the storms to grow to great height. They take on a characteristic anvil shape with very thick, dark cumulus clouds in the body and an abruptly flat top that drags behind the storm. The intense circulation in both directions can draw the freshly condensed rain to high levels, where it can freeze, fall, condense more moisture, and be swept back upward to have a new coat of ice added to it. A number of such cycles, as is common in a supercell, produce hail, the size of which depends upon the number and intensity of the cycles it travels through. A strong upward and downward motion is also necessary to produce a tornado. That is why hail is commonly associated with tornadoes.

Surprisingly, many of the storms that bear tornadoes begin with horizontal rather than vertical motion. A burst of cool, dry air at height rides over warm, moist air at ground level. The cool air is denser and sinks, while the less dense warm air rises. This creates a rolling effect, or horizontal rotation, in the now-unstable atmosphere. As the result of instability of the cold airflow, variations along the length of the horizontal rotation, and drag on the surface, the developing storm flips up on end to produce a vertically rotating, or spinning, cell. The cell may spin either counterclockwise, as is common for all low-pressure disturbances in the Northern Hemisphere, or clockwise. The now-vigorously-spinning mesocyclone develops into a supercell. Although the upward motion makes the storm grow strong, it is the downward motion that forms the tornado. The first sign of the downward motion is the development of mammatus clouds. Next, a wall cloud extends below the storm. The wall cloud is a circular band of clouds that hang below the main cloud deck. It is from the center of the wall cloud that the tornado drops.

Supercells with tornadoes are not symmetric. Part of the storm is dominated by updraft and part by downdraft. The updraft area is characterized by

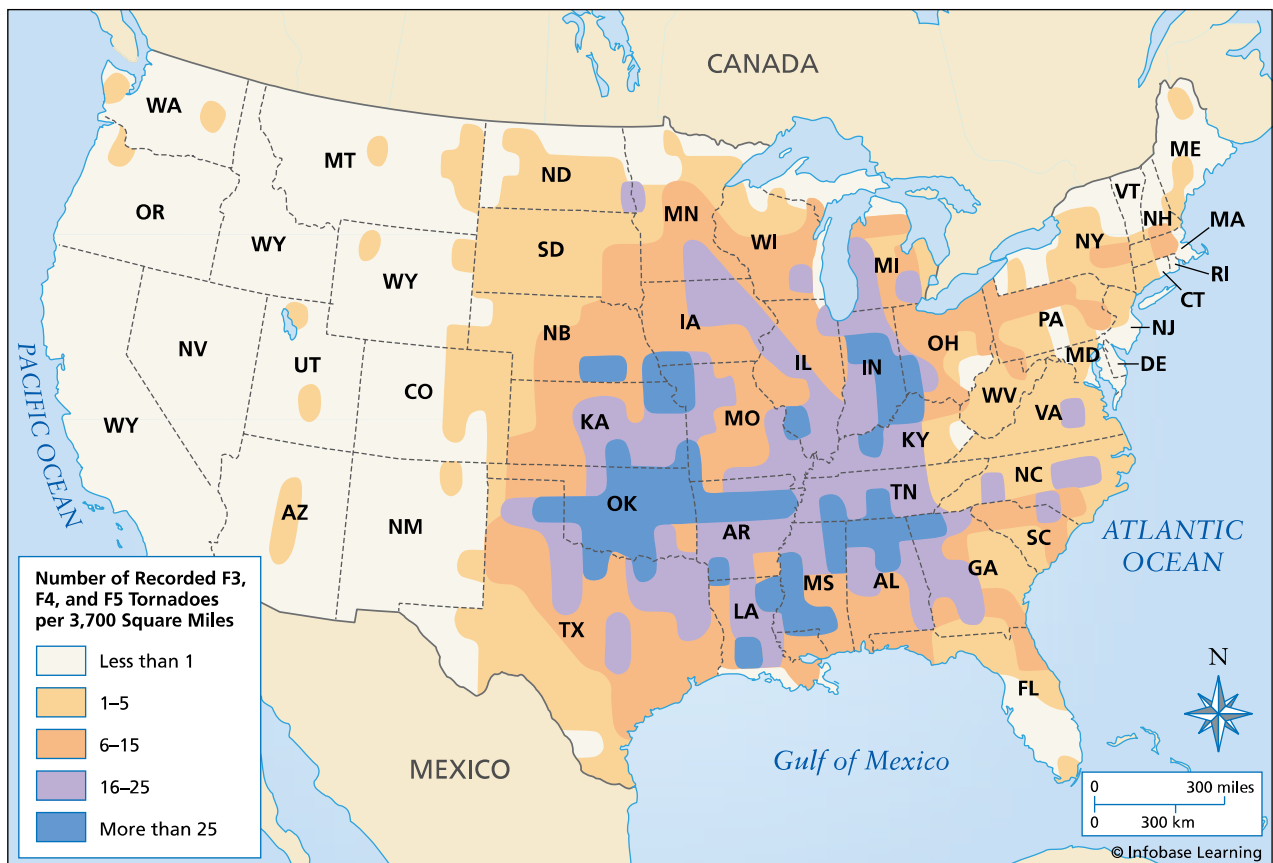

**Three-step model for the development of a tornado. The first step (top) is the convergence of oppositely directed cold air aloft and warm air below, causing horizontal rotation. In step two (middle), the horizontally rotating cell is swept upward by rising air to produce a large rotating cloud mass called a supercell storm or mesocyclone. In step three (bottom), if conditions are right, a tornado is spawned beneath the mesocyclone accompanied by thunderstorms.**

heavy rain, whereas the downdraft area is relatively dry. This means that the tornado is on the dry side of the storm. In many storms, the tornado occurs on the southwest side of the storm. It can be seen on the Doppler radar used by meteorologists as a distinct hook in the intense, or “red,” part of the storm.

### CLASSIFICATION OF A TORNADO

The classification of the strength of a tornado is based purely upon wind speed. The standard classification scheme up until 2007 is known as the Fujita scale: It typically ranges from F0 to F5, though F6 (*F* for *Fujita*) tornadoes are possible in extremely rare cases. These F classifications are designated according to the following criteria:

- **F0 tornadoes.** Also known as gale tornadoes, F0 storms have wind speeds of 40–72 miles (64–116 km) per hour. They produce some damage to chimneys, break branches off trees, push over shallow-rooted trees,
- and damage sign boards. The frequency of this level of storm is 29 percent of total, though other data suggest that with F1 they constitute about 74 percent.
- **F1 tornadoes.** These are classified as moderate tornadoes with wind speeds of 73–112 miles (117–180 km) per hour. The damage from these storms includes peeling the surface off roofs, pushing mobile homes off their foundations or overturning them, pushing moving autos off roads, and possibly destroying attached garages. The frequency of this level of tornado is about 40 percent.
- **F2 tornadoes.** These storms are classified as significant tornadoes with wind speeds of 113–157 miles (181–252 km) per hour. They inflict considerable damage including tearing roofs off frame houses, demolishing mobile homes, pushing over train boxcars, uprooting or breaking large trees, and turning light objects into missiles. The frequency of this

**Map of the United States summarizing the annual distribution of F3, F4, and F5 tornadoes, which averaged more than 3,700 square-mile (9,583 km<sup>2</sup>) blocks between 1950 and 1998. (The greatest risk is in the central and southern Midwest.)**  
 (Source: NOAA, Storm Prediction Center Statistics)

level of tornado is about 24 percent, though other data suggest that with F3 storms they make up 25 percent of the total.

- *F3 tornadoes.* These severe tornadoes have wind speeds of 158–206 miles (253–330 km) per hour. Damage from them is intense, including tearing the roof and some walls off well-constructed houses, overturning trains including the engine, and uprooting most trees in the forest. The frequency of this level of tornado is about 6 percent.
- *F4 tornadoes.* These devastating tornadoes have wind speeds of 207–260 miles (331–417 km) per hour. They can level well-constructed houses and hurl structures with weak foundations for some distance. Cars are thrown and large objects can become missiles. Only about 2 percent of storms reach this strength, though some studies suggest that with F5 tornadoes they constitute only about 1 percent of the total.
- *F5 tornadoes.* These incredible tornadoes have wind speeds of 261–318 miles (418–509 km) per hour. If these storms strike, strong frame houses are lifted off foundations and carried considerable distances before disintegrating. Massive missiles are sent flying for distances in excess of 325 feet (100 m). They can remove the bark from trees and badly damage steel-reinforced concrete structures. Far less than 1 percent of tornadoes reach this intensity.
- *F6 tornadoes.* Only one or two of these inconceivable tornadoes with wind speeds of 319–379 miles (510–606 km) per hour have ever been proposed, much less documented. If this level is ever achieved, evidence for it might only be found in some manner of ground swirl patterns. The damage is so intense that it may never be identifiable through engineering studies.

Over the years, the Fujita scale has revealed several weaknesses. It is a very subjective scale in that it is based solely on the damage caused by the tornado. It does not distinguish the damage among different types of construction. It is difficult to apply in the absence of damage indicators. For example, if the  $\frac{3}{4}$ -mile- (1.2-km-) wide tornado does not hit any structures, a Fujita scale designation cannot be assigned. It is subject to bias of observers and is based on the worst damage observed even if it is one build-

ing or house that shows such damage. It also overestimates wind speeds in tornadoes greater than F3. For these and other reasons, the meteorological profession abandoned the Fujita scale for the Enhanced Fujita scale.

The Enhanced Fujita (EF) scale was implemented in the United States on February 1, 2007. The EF scale relies on 28 designated damage indicators to determine the tornado's rating. Each one of these indicators has a description of the typical construction for that category of indicator. The degree of damage (DOD) can then be determined by observation for each indicator present. By comparing the DOD with a calibrated guide, an expected estimate of wind speed can be determined. The damage observed is assigned a lower and an upper bound of wind speed. The following table is a list of the 28 features from which wind speed may be estimated.

By using as many features as can be identified, the wind speed can be estimated. The advantage of this system is that there are multiple sources of estimation including vegetation. This is much more inclusive and ostensibly more accurate than the old Fujita scale. The wind speed is interpreted for a three-second gust and the EF scale is assigned. The scale is as follows:

EF-0	65–85 miles (104–137 km) per hour
EF-1	86–110 miles (138–177 km) per hour
EF-2	111–135 miles (178–217 km) per hour
EF-3	136–165 miles (218–264 km) per hour
EF-4	166–200 miles (265–320 km) per hour
EF-5	>200 miles (320 km) per hour

Although they are supposed to be converting to the EF scale, most weather reports in the media still rely on the older Fujita scale. For most purposes, the older scale is still descriptive enough to rate tornadoes in terms of power, and it is easier to understand for most people. For technical purposes, the EF scale is superior. Environmental effects of tornadoes are better classified by the EF scale because small variations in damage can greatly affect the amount of pollutant released as the result of a tornado. The EF scale is also superior for planning purposes such as building codes for facilities that could release toxicants during a tornado. In this case, the small differences could be the difference between repairable damage and an environmental disaster.

## PATH OF A TORNADO

By far, most funnel clouds that descend from the base of a storm do not reach the ground. Many funnel clouds are generated, but few become tornadoes.

### STRUCTURES WHOSE DAMAGE IS USED TO DETERMINE RANK ON ENHANCED FUJITA (EF) SCALE

1)	Small barns, farm outbuildings (SBO)
2)	One- or two-family residences (FR12)
3)	Single-wide mobile home (MHSW)
4)	Double-wide mobile home (MHDW)
5)	Apartment, condominium, townhouse (three stories or less) (ACT)
6)	Motel (M)
7)	Masonry apartments or motel (MAM)
8)	Small retail building (fast food, etc.) (SRB)
9)	Small professional building (doctor's office, branch bank) (SPB)
10)	Strip mall (SM)
11)	Large shopping mall (LSM)
12)	Large, isolated ("big box") retail building (LIRB)
13)	Automobile showroom (ASR)
14)	Automotive service building (ASB)
15)	School: one-story elementary (interior or exterior halls) (ES)
16)	School: junior or senior high school (JHSH)
17)	Low-rise (one- to four-story) building (LRB)
18)	Midrise (five- to 20-story) building (MRB)
19)	High-rise (more than 20 stories) (HRB)
20)	Institutional building (hospital, government, or university) (IB)
21)	Metal building system (MBS)
22)	Service station canopy (SSC)
23)	Warehouse (tilt-up walls or heavy timber) (WHB)
24)	Transmission line tower (TLT)
25)	Free-standing tower (FST)
26)	Free-standing pole (light, flag, luminary) (FSP)
27)	Tree—hardwood (TH)
28)	Tree—softwood (TS)

Most tornadoes begin as low-rank storms (EF-0) and may ascend and descend several times before becoming established. Once they are descended, or "on the ground," they can intensify. They typically

begin as low, short, and thin funnels. As they intensify, the funnel grows wider and lengthens. The path of the tornado is variable. Some travel in straight paths, whereas others tend to sweep back and forth. The longer the funnel, the more they sweep. The forward speed of a tornado is also variable, ranging from 20 miles (32 km) per hour to upward of 60 miles (96 km) per hour. The forward speed impacts the total wind speed just as it does with hurricanes. Where the wind direction is parallel to the movement direction, the wind speed and forward speed are added to produce a high-velocity side. In most tornadoes, this is the right side of the tornado in the United States. On the left side, the forward motion is subtracted from the wind speed, producing lower wind speeds, in most cases.

Toward the end of the life of the tornado, it may become ropey and make strange patterns. Tornadoes primarily stay on the ground for a few seconds to a few minutes, especially for low-rank storms. Larger storms remain on the ground for longer periods. They can be as short as 30 minutes or less and as long as three hours in the most severe cases.

### POLLUTION FROM A TORNADO

Pollution from a tornado can have a number of sources. The first sighting of a tornado on the ground is typically the debris that continuously emanates from the storm in all directions. A tornado may generate several tons of debris that can spread all over the countryside. The debris can include fragments of all kinds of construction materials, many of which can be hazardous. The strong winds pulverize much of the material and produce a huge amount of dust or particulate that may circulate around the area for days, depending upon the amount of ensuing rain. The particulate may include leaded paint, asbestos, glass fibers from insulation, and a number of other pollutants.

The other main source of pollution is generated by the structures that are destroyed by the intense wind. Facilities, including manufacturing plants and storage tanks, can be ruptured or destroyed in a tornado. This would create a spill that would enter the surface runoff, eventually entering surface waters. Most spills would be fuel of some sort, but in areas of chemical manufacturing, they could be a number of possible chemicals. Other commercial enterprises could also store dangerous chemicals such as trichloroethylene (TCE) in dry cleaners that would also enter the soil or water. Tanker train cars can also be carrying dangerous chemicals that can be released if they are ruptured. These spills have serious environmental consequences. There was even a possible

doomsday scenario in a movie of a tornado destroying a nuclear power plant and causing a meltdown. Although this has never happened, it is not out of the question.

**Torrey Canyon oil spill Scilly Islands, United Kingdom (March 18–30, 1967) Water Pollution** As one of the world's first supertankers, the *Torrey Canyon* was the 13th largest ship ever in commercial service (120,000 tons [108,862 metric tons]). Originally built in the United States in 1959 as a standard-sized (60,000 tons [54,431 metric tons]) tanker, it was cut in half and enlarged in Japan. With the addition of several new cargo bays, at almost 1,000 feet (305 m) long and more than 125 feet (38 m) wide, it thus became a supertanker, an oceangoing vessel with a capacity of more than 75,000 tons (66,964 metric tons). Supertankers were being developed to meet the demands of the United States and Europe for inexpensive Middle Eastern oil. Proven petroleum reserves in the known developed oil fields began to decline after World War II, and the price of oil started to rise. This made Middle Eastern supplies more economically attractive. The problem was getting the oil to market. There were few overland pipelines and none that could effectively connect wellheads in Kuwait or Iraq to refining and distribution centers in New Jersey, Louisiana, or Milford Haven, United Kingdom, and supertankers were the solution. Crude oil could be extracted and stored in the Middle East and loaded in enormous quantities

onto large vessels that can carry it directly to market for final processing and sale. However, risks were associated with moving such large quantities of toxic substances through and near ecologically sensitive and fragile ocean and estuarine settings.

### BACKGROUND

The supertanker *Torrey Canyon* was owned by Union Oil of California but had been chartered to British Petroleum (BP). It was registered in Liberia and was operated by a mostly Italian crew. It picked up a cargo of about 30,000,000 gallons (114 million L) of crude oil at Mena al-Ahmadi, Kuwait, on February 17, 1967. After about a month of uneventful sailing, the ship had rounded the Cape of Good Hope (too big to fit through the Suez Canal), passed the Canary Islands, and, by the evening of March 17, had reached the Isles of Scilly off the coast of England. The ship's destination was Milford Haven, a major industrial port in southeastern England. The *Torrey Canyon* was to unload its cargo at a BP refinery and begin preparations for the return voyage to the Middle East.

The standard approach to Milford Haven for a ship the size of *Torrey Canyon* was to sail seaward (east) of the Scilly Isles. Otherwise, it would have to

The grounded U.S. tanker *Torrey Canyon* on a reef off the Scilly Islands, England, March 1967 (AP Images)

thread its way through a narrow (20-mile- [32-km-] wide) gap between Lands End, a spit of land jutting from the east coast of Cornwall, and the rock-strewn coast of the Scillys. The Scilly Islands enjoy almost year-round sunshine, because of the moderating ocean climate. They are a popular vacation spot and tourist attraction. Among the islands' main exports are flowers, which, because of the almost year-round sunshine and relatively mild climate, begin to bloom much earlier there than in other parts of the United Kingdom. Bird-watchers are also attracted to the Scillys, because rare species from all parts of Europe commonly use the islands to rest and eat before continuing seasonal migrations.

There are 55 islands in the archipelago, five inhabited and 50 without permanent residents, as well as some 90 large half-submerged rocks. The islands are small, with Saint Mary's, the largest, only three miles (4.8 km) across. They are composed of granite, which weathers into a gritty soil and produces light-colored, sandy beaches. The blocky cliffs and the submerged rocks circling many of the islands have long been known to pose a serious threat to shipping.

### THE ACCIDENT AND OIL SPILL

Most environmental disasters are not caused by a single event, but rather a series of small actions, which combine into a catastrophe. The *Torrey Canyon* oil spill is a good example. As the ship neared the end of its 6,000-mile (9,656-km) trip, a navigational error caused it to enter the relatively narrow waterway between Lands End and the Scilly Isles. These are very dangerous waters for a ship as big and as difficult to maneuver as the *Torrey Canyon*. The captain was made aware of the error and yet issued a "hold course" order. It was later found that if the *Torrey Canyon* did not make Milford Haven by the next day, it would have had to wait six days for a tide high enough to allow it to enter the shipping channel and dock. The *Torrey Canyon* continued under way at almost full speed, 17 knots or about 20 miles per hour (32 km/h).

The captain and crew were not particularly concerned because the seas were calm, the weather clear, the charts accurate and up-to-date, and the ship one of the most modern and reliable vessels ever built. As long as they stayed well clear of the Scillys, particularly the notorious Seven Stones Reef, an area of submerged granitic boulders, the *Torrey Canyon* was not in any real danger. An inexperienced junior officer on his first trip, however, made a second navigational error, plotting the location of the ship well clear of Seven Stones when actually it was within three miles (4.8 km) of these hazards. The

captain discovered the error just in time and quickly ordered a series of emergency course changes. The ship failed to respond, however, because the helmsman neglected to disengage the autosteering mechanism, which had been preset to maintain the most direct course to Milford Haven. On March 18, 1967, the *Torrey Canyon* struck Pollard's Rock in Seven Stones Reef and a 17-foot- (5.2-m-) long gash was ripped through six of the oil storage compartments. Over the next 12 days, the ship's entire cargo of 36 million gallons (136 million L) of crude oil was released into one of the most ecologically sensitive and pristine areas of the British Isles.

This was the first major spill from a supertanker, and no one was sure how to respond. The crew was evacuated with one lost at sea during the rescue effort, and a Dutch salvage company attempted to refloat the vessel by removing it from the reef. A second crewman was killed in an explosion as salvage crews attempted to transfer the oil remaining onboard to another tanker. As a result, other recovery efforts were quickly abandoned. As oil continued to leak from the gashes, the Royal Navy decided to bomb the *Torrey Canyon* and set the rapidly spreading oil slick on fire using napalm. Fighter jets dropped almost 100 incendiary bombs on the stationary ship, many of which missed their target. They were eventually successful in blasting the stricken vessel off the reef and sending it to the ocean bottom. Some of the floating oil was also ignited in the attack. All of this was done under the watchful eye of the British prime minister Harold Wilson, who was vacationing on the Scilly Islands when the *Torrey Canyon* went aground. Unexploded ordnance warnings are still in effect for divers who wish to explore the sunken wreck of the *Torrey Canyon*.

### THE CLEANUP

The oil slick released by *Torrey Canyon* spread out to cover an area of 270 square miles (700 km<sup>2</sup>). Approximately 120 miles (192 km) of English coastline and 50 miles (81 km) of beach in France was contaminated. A variety of cleanup efforts were used on the oil that was fouling these shorelines. Some 1,400 British soldiers were mobilized and, using a quickly formulated mix of naturally absorbent straw and grose (a haylike weed), recovered about 1 million gallons (3.8 million L) of oil. The French also used chalk mixed with stearic acid, a waxlike solid used in soaps, to absorb and break down the oil washing up on their beaches. Five million gallons (18.9 million L) of oil treated in this manner was recovered by more than 3,000 French troops working for weeks after the spill.

At sea, skimmer pumps recovered oil floating on the water, and more than 40 ships began to release more than 10,000 tons (9,072 metric tons) of detergents to emulsify and disperse the oil. Unfortunately, although the dispersant was reasonably effective at breaking up the floating petroleum, these previously untested chemicals proved to be extremely toxic to marine life. Later studies showed that the dispersants did more ecological damage than the oil. Wave-beaten rock and beaches that received only a light oiling recovered in about five to eight years. Similar areas that received a coating of dispersant took nine to 10 years to return to their ecological prerelease state. Along those stretches of beach where dispersants were extensively and repeatedly used, many types of marine flora and fauna have still not reappeared.

The spill occurred during the peak of the northern migration for many varieties of birds. Several studies estimated the number of birds killed at about 200,000. There was a 1 percent survival rate for the thousands of oil-covered birds picked up from beaches by volunteers. With the best of intentions, volunteers washed the birds with detergents to remove the crude oil. This washing also removed the natural coating of oil seabirds need to repel water and retain body heat. Also, as the birds preened, they ingested residual amounts of detergent, which either fatally poisoned them or made them extremely ill.

### THE AFTERMATH

The long-term environmental and economic effects of the spill were devastating. More than 40 percent of the 1967 oyster harvest was destroyed. Oysters are an important dietary as well as financial supplement for island residents. There was a literal explosion of seaweed and algal growth levels as a result of the nitrogen and other nutrients present in the dispersants that dissolved into the seawater. This overwhelmed native marine plants and disrupted the local food web for many years. There was an 80 percent drop in tourism. It would take another five years to recover to prespill levels. The human costs included the two fatalities that occurred during the evacuation and attempted salvaging of the *Torrey Canyon*. The ship's captain, after having his license revoked for incompetence, died several years later. The largest insurance claim in maritime history to that date was filed for the incident at \$16 million for the ship and \$23.2 million for the cleanup, including the RAF bombardment.

The incident, however, drew attention to the potential for such disasters. In 1969, the international Civil Liability Convention (CLC) was estab-

lished. The CLC held shipowners strictly liable for environmental and ecological damage caused by the release of oil, whether or not that release occurred because of accident, mechanical failure, or negligence. A few years later in 1973, the International Convention for the Prevention of Pollution from Ships was adopted. This treaty set operational and performance standards for oil tankers and other commercial vessels involved in the transport of hazardous or potentially hazardous cargo.

**toxaphene** When dichlorodiphenyltrichloroethane (DDT), the most widely used pesticide, was banned in 1972, there was an urgent need for a replacement. Toxaphene replaced DDT as the pesticide of choice for the mid- and late 1970s. The problem was that toxaphene is probably more toxic than DDT and nearly as persistent in the environment. For that reason, it, too, was banned in the United States in 1982, and another pesticide had to be found. Toxaphene is a chlorinated organic pesticide that is a mixture of at least 175 and as many as 670 separate compounds. It is also known by trade and chemical names such as Chlorinated camphene, Octachlorocamphene, Camphochlor, Agriocide Maggot Killer, Alltex, Crestoxo, Compound 3956, Estonox, Fasco-Terpene, Geniphene, Hercules 3956, M5055, Melipax, Motox, Penphene, Phenacide, Phenatox, Strobane-T, Toxadust, Toxakil, Vertac 90 percent, Toxon 63, Attac, Anatox, Royal

Brand Bean Tox 82, Cotton Tox MP82, Security Tox-Sol-6, Security Tox-MP cotton spray, Security Motox 63 cotton spray, Agro-Chem Brand Torbidan 28, and Dr Roger's Toxene. It has been found in 58 of the first 1,430 U.S. Environmental Protection Agency (EPA)-designated Superfund sites (National Priority List) in which it has been tested. As a result of the widespread distribution and adverse health effects from exposure, it was ranked number 31 on the 2007 CERCLA Priority List of Hazardous Substances, which includes 275 pollutants.

### PROPERTIES, USES, AND PRODUCTION

Toxaphene is an organochlorine insecticide that is one of the polychlorinated bicyclic terpenes with chlorinated camphers. In its base form, it is a yellow or amber waxy solid with a turpentine odor; it was marketed as wettable powders, emulsifiable concentrates, granules, dusts, oils, and emulsions. Toxaphene was first commercially produced in 1947 and more than 900,000 tons (409,000 metric tons) was reportedly produced between then and 1974. Peak production in the United States was in 1975 at 59.4 million pounds (27 million kg) but declined 90 percent by 1982 because of the bans and restrictions. The average consumption in the United States between 1966 to 1979 was 34 million pounds (15.5 million kg) per year. By 1977, the annual consumption was up to 40 million pounds (18.2 million kg) per year but dropped to 6.6 million pounds (3 million kg) by 1982, when its use in the United States was banned. During peak consumption, 85 percent was used for cotton, 7 percent for insects on livestock and poultry, 5 percent for other field crops, 3 percent for soybeans, and 1 percent for sorghum. Over its entire history, 50 percent was used for cotton, 17 percent for vegetables, 17 percent for livestock, and 12 percent for soybeans. It was effective against all major cotton insects, mealybugs, worms, scab mites, hornflies, lice, armyworms, cutworms, and grasshoppers, as well as control of certain species of fish in lakes. It is still used for mealybug and moth control on pineapples, and weevil control on bananas in the Virgin Islands and Puerto Rico, among others.

### ENVIRONMENTAL RELEASE AND FATE

As with other pesticides, virtually all toxaphene that was produced was released as nonpoint source pollution in widespread dispersion. Since the ban, it has only been released as point source pollutant from leaks and spills at production, transportation, storage, and waste facilities in the United States. Toxaphene was primarily released into the soil, where

evaporation from the surface was a significant form of removal (15.4–30.8 pounds [7–14 kg] per hectare per year). That which did not evaporate adhered strongly to soil, where it does not hydrolyze, photolyze, or biodegrade to any extent under aerobic conditions. The half-life of toxaphene in soil has been calculated at one to 14 years, but one study found 45 percent of that which had been applied in 1951 was still present 20 years later. The biodegradation under anaerobic conditions is much faster, with a half-life as quick as six weeks. Very little toxaphene leaches into the groundwater system, but erosion of toxaphene-bearing soil can result in surface water contamination. In surface water, that which does not evaporate from the surface adheres to particles in the water and settles into the sediment, where it is also impressively persistent. In one study of Canadian lakes that had been treated for unwanted fish species, toxaphene was still found to be at toxic levels five years after the application. In the atmosphere, toxaphene is also very persistent though not as persistent as in soil. It typically attaches to particulate and slowly breaks down by photolysis and photochemical reactions with hydroxyl radicals. Transport in the atmosphere has been found to be up to 750 miles (1,200 km).

Perhaps even more impressive than its persistence is toxaphene's ability to bioaccumulate. Bioconcentration factors for fish have been found to range from 3,100 to 69,000 times ambient levels. Other aquatic and terrestrial organisms also show bioaccumulation but not to this degree. It is primarily through consumption of animals with bioaccumulated toxaphene that humans are exposed to it.

### TOXICOLOGY AND HEALTH EFFECTS FROM EXPOSURE

Exposure to toxaphene results in numerous adverse health effects. Acute exposure first causes nausea and vomiting but primarily causes effects on the central nervous system including hyperexcitability, restlessness, muscle tremors and spasms, and periodic to continuous convulsions, possibly leading to brain damage and even death by respiratory failure at high doses. It can also cause hyperthermia; paresthesia of the tongue, lips, and face; skin irritation; and damage to the liver. Long-term chronic exposure results in headaches, nausea, fatigue, muscle twitching, vision problems, and damage to the liver, kidneys, adrenal glands, blood system, and immune system, depending upon dosage. It has also been shown to cause minor changes in fetal development and decreased fertility in laboratory animals. Toxaphene is regarded as reasonably anticipated to be

a human carcinogen by the Department of Health and Human Services. It has been shown to cause increased incidence of cancer of the liver and thyroid in laboratory animals, but there is no indication of cancer in humans at this point.

### REGULATIONS ON HUMAN EXPOSURE

The EPA banned the use of toxaphene in the United States and its territories in 1990 and the import of any food with toxaphene residues in 1993. They limit the amount of toxaphene in drinking water to three parts per billion (ppb) under the Safe Drinking Water Act. They further require that the release of one pound (0.45 kg) or more must be reported to the National Response Center. OSHA set their permissible exposure limit (PEL) to 0.5 milligram of toxaphene per cubic meter of workplace air during an eight-hour-workday, 40-hour workweek.

**toxicology** Under most legal definitions, poisons are chemicals that cause illness, injury, or death when taken in small quantities, usually about 50

mg per 1 kg of body weight or less. This is about  $\frac{3}{4}$  teaspoon (3.7 mL) for the average adult and about  $\frac{1}{8}$  teaspoon (0.6 mL) for a two-year-old child. The word *poison* is from the Latin *potio*, which means "drink." Their effect has to be immediate or very near term, and most toxicologists classify a poison as having an LD50 of 50 mg or less. LD50 means that a substance has a lethal effect at 50 mg per 1 kg of body weight (LD or lethal dose) on 50 percent of the test population within 14 days. Toxicologists have measured LD50s on many substances: aspirin, for example, has an LD50 of 1,000 mg per 1 kg of body weight; caffeine's LD50 is 192 mg; and sodium cyanide has an LD50 of 6 mg (see the following table).

People have been poisoning each other intentionally for thousands of years. The Romans became particularly adept at using poisons, even establishing special "poison schools" to teach and pass along the craft to promising students and future generations. Professional poisoners often tested the potency of their formulas on animals, slaves, or convicts. Poisons available during Roman times were developed from three sources: animals, minerals, and plants. Animal poisons were not well studied in ancient times, being difficult to extract and store. Cantharadine, a skin irritant formed from the husks of dried blister beetles (later called Spanish fly), was popular, as were such unlikely poisons as bull's blood, toads, and salamanders. Venom from poisonous insects, snakes, spiders, and scorpions was well known but rarely used in homicide. Mineral poisons, primarily lead, mercury, copper, arsenic, and antimony salts, also were known but seldom used. The fatal doses were high and difficult to introduce into food or water because of their distinctive taste.

Poisons made from plants were most frequently used. They included extracts from henbane, datura, deadly nightshade, mandrake, aconite from monkshood, hemlock, hellebore, colchicum from autumn crocus, yew, and opium. Cyanide (LD50 1.1 mg), distilled from peach, apple, and other fruit pits, was used in judicial executions by the ancient Egyptians ("penalty of the peach") and Romans ("the cherry death"). Cyanide also was used as arrow and dart poison by the Mayan, who extracted it from the yucca plant. Strychnine, one of the deadliest poisons ever developed (LD50 of 0.2 mg), was apparently not known to the Romans but was used in India, where it was extracted from the seeds of the *Strychnos nux-vomica* tree.

Poisons are different from toxins, although both scientists and nonscientists often use the two terms interchangeably. Strictly speaking, toxins are substances produced by biological activities that cause

## TOXICITY RATING AND DOSAGE FOR SEVERAL SUBSTANCES

Toxicity Rating <sup>1</sup>	Comparable Oral LD50 (single dose to rats) mg/kg	Probable Lethal Dose for Adults	Substance	Oral LD50 (mg/kg) <sup>2</sup>
Extremely toxic	1 or less	one drop (1 grain)	Aldicarb (insecticide)	1
Highly toxic	1–50	1 tsp (4 mL)	Parathion (insecticide) Kerosene	3 5–49
Moderately toxic	50–500	1 fl. oz. (30 mL)	Nicotine Caffeine	53 192
Slightly toxic	500–5,000	1 pint (600 mL)	Codeine Aspirin	600 1,240
Practically nontoxic	5,000–15,000	1 quart (1 L)	Sodium Chloride (table salt)	3,320
Relatively harmless	15,000 or more	1 quart (1 L)	Sucrose (table sugar)	29,700

Notes: (1) Toxicity rating based on the Hodge and Sterner Toxicity Class scale

(2) Oral LD50 taken from NIOSH Registry of Toxic Effects of Chemical Substances

injury, illness, or death at low concentrations. Examples include the bacterial proteins that cause tetanus and botulism. Modern usage, however, has broadened the definition of *toxic* to include harmful substances that are nonbiologic in origin (e.g., toxic waste).

Toxicologists evaluate the effects of poisons primarily through the use of animal studies (i.e., experiments on rats, monkeys, guinea pigs, etc.). These studies provide general information on how poison is metabolized or incorporated into the physiological systems of animals. They also provide clues as to how these substances may affect human health.

An important component in the understanding of poisons is that of dose. A dose is a quantity or amount of an active agent that is taken into the body at any one time. Most commonly associated with medicine, dose can also be applied to the accidental, unintentional, or unknowing intake or ingestion of a poisonous or toxic substance. There is a saying among toxicologists that the “dose makes the poison.” The inhalation of a 0.7-ounce (20-mg) mist of cromolyn sodium solution dissolved in 0.06 fluid ounce (2 mL) of water is a very effective treatment for asthma. At much higher concentrations, it may cause adverse reproductive effects in pregnant women. Almost every substance can be toxic. Water, which humans need to consume about one half-gallon (2 L) of every day, has a 28-hour LD50 of 180,000 mg per 1 kg of body weight. If a person weighs 150 pounds (68 kg) and drinks about five gallons (19 L) of water in less than a day, there is a good chance he or she will become very sick or even

die. That quantity of water consumed over so short a time quickly dilutes electrolytic balances, and the excess fluid interferes with respiration, cardiac activity, and brain function.

Generally, as dose increases, toxicity increases, but this varies with the substance. The toxic effects of many substances do not become apparent until a minimal amount is ingested. This is called the threshold dose, and it is the lowest dose or concentration that causes a detectable response in a population. Above the threshold dose, a response is induced—people become sick or die. Below the threshold, there is no observable effect or response. This relationship is illustrated in a dose-response curve, which tracks the adverse response that will occur with any given dose. For example, in a dose-response curve for smokers, mortality rates are plotted against the quantity (or dose) of cigarettes smoked. As the number of cigarettes smoked per day (dose) increases, so does the mortality rate (response).

## TOXIC EFFECTS ON ORGANISMS

When a toxic or poisonous compound enters an organism, it has an acute, chronic, or subchronic effect. Acute toxic effects occur when a single dose or amount of a substance causes severe biological harm (sickness or injury) or death shortly after exposure (usually within 24 hours). For example, when a prison inmate is injected with a high concentration of potassium chloride, acute toxicity results. This method of execution (lethal injection) quickly

results in death because it disrupts the neurological mechanisms that signal the heart to contract.

In chronic toxicity, illness or death is caused by repeated or long-term exposure, usually over more than 50 percent of an organism's life span, to low doses. For humans, chronic exposure typically occurs over several decades. For experimental animals (laboratory rats or mice), chronic exposure is typically considered to be more than three months. For example, in 1997, 25,000 people died in the United States of cirrhosis, a chronic liver disease caused by repeated, long-term exposure to alcohol. From an environmental perspective, chronic toxicity is more commonly associated with chemicals that bioaccumulate. In the late 1950s, in Minimata, Japan, hundreds of people became chronically ill (most had central nervous system damage) through the daily, long-term ingestion of fish from waters that were severely polluted with mercury.

Subchronic toxic effects are observed after repeated daily exposure over a significant part of an organism's life span, usually not exceeding 10 percent. For people, this may mean exposures of less than 10 years. For experimental animals, the period of exposure may range from a few days to six months. In practice, subchronic exposures are longer than acute exposures, but shorter than chronic exposures.

Beryllium is an alloying material used in the manufacture of high-performance aircraft parts and missile components. As a result of its widespread industrial applications, toxicologists have been able to determine that an acute health effect (berylliosis) occurs when people inhale beryllium dusts at concentrations ranging between 2 and 1,000 mcg/m<sup>3</sup>. Berylliosis develops shortly after exposure to these types of high concentrations and is characterized by inflammation of mucus membranes, oral and nasal cavities, tracheae, and bronchial tubes. It may progress to severe pulmonary symptoms. Longer-term exposures to lower concentrations may result in the development of chronic berylliosis. This form of the disease is highly variable in onset and is more likely to be fatal. Chronic berylliosis primarily affects the pulmonary system and is characterized by the development of scar tissue that stiffens the lungs and can eventually make breathing impossible. For subchronic exposures to beryllium, some studies suggest that the human health consequence may be cancer.

There are other types of health effects caused by exposure to toxic substances. Local health effects occur when a toxic substance has contact with the body—on the hand or eyes or in the lungs. If skin

is splashed with a strong acid, the resulting burn is a local health effect. A systematic effect takes place when the toxic substance enters the body and damages a specific physiological or neurological function—liver, kidneys, or bone marrow. Chronic exposures to low levels of arsenic cause hematological (blood-related) systematic damage to veins and arteries, increased blood pressure, and severe anemia. Synergistic effects occur when the body is exposed to two or more toxic substances at the same time. The combined effect can be greater than the individual effects. For example, most smokers face a one in 10 to one in 20 chance of developing lung cancer. This risk, however, increases 50–90 times if a smoker is also exposed to asbestos. Nonsmokers have a one in 200 chance of developing lung cancer.

Each of the effects described (acute, chronic, local, etc.) can be related to a specific toxic substance (asbestos, arsenic, etc.). The following table provides a list of common environmental contaminants and their toxic effects on the body. These health effects can be more broadly classified into two main types of categories: those that cause cancer (carcinogenic) and those that have other health effects (noncarcinogenic).

## CARCINOGENIC HEALTH EFFECTS

*Cancer* is the term used to describe a group of diseases that form fast-growing and usually fatal accumulations of abnormal cells called neoplasms. The unstructured mass resulting from the neoplasm's development is a tumor, which does not obey or follow the biological control mechanisms that govern the growth and function of an organism's cells. Tumors simply grow for the sake of growing and provide no biological service or value for the host organism.

Tumors can be classified as either benign or malignant. Benign tumors grow more slowly than malignant ones, and the tissue of a benign tumor is structured in a manner similar to that of the tissue from which it is derived. The tissue of a malignant tumor, however, has an abnormal and unstructured appearance. The most important distinguishing feature between benign and malignant tumors is that benign tumors do not metastasize. That is, benign tumors do not spread or begin to grow in places other than their point of origin. *Cancer* is a term used to describe a malignant neoplasm or tumor that is moving or has moved beyond its point of origin. *Tumor* is used to denote a mass of neoplasm that is readily distinguishable and confined in the surrounding, normal living tissue.

### SOURCES AND HEALTH EFFECTS FROM EXPOSURE TO ENVIRONMENTAL CONTAMINANTS

Category	Name	Health Effect	Sources
Metals	Arsenic	Skin damage and circulatory problems; increased risk of cancer	Semiconductor manufacturing, petroleum refining, wood preservatives, erosion of natural deposits
	Beryllium	Intestinal lesions	Discharges from metal refineries, coal processing plants, and electrical/aerospace industries
	Cadmium	Kidney damage	Corrosion of galvanized pipes, discharges from metal refineries, and erosion of natural deposits
	Lead	Developmental effects (brain damage) in infants and children	Corrosion of household plumbing fixtures and erosion of natural deposits
	Mercury	Kidney damage	Discharges from refineries and factories where mercury is used; runoff from landfills and erosion of natural deposits
Volatile organic compounds	Benzene	Anemia with decrease in blood platelets; increased risk of cancer	Discharges from factories where organic chemicals are used; leaching from waste disposal sites
	Ethylbenzene	Liver or kidney damage	Discharges from petroleum refineries
	Tetrachloroethene	Liver damage; increased risk of cancer	Discharges from industrial facilities and dry cleaners that use solvents
	Toluene	Nervous system, kidney, and liver damage	Discharges from petroleum refineries
	Trichloroethene	Liver damage and increased risk of cancer	Discharges from industrial facilities that use solvents
Semivolatile organic compounds	Benzo(a)pyrene	Damage to reproductive systems and increased risk of cancer	Leaching from linings of water storage tanks and distribution lines
	Di(2-ethylhexyl) phthalate	Damage to liver and reproductive systems; increased risk of cancer	Discharges from rubber and chemical factories

If exposure to a substance is known to produce cancer, it is classified as carcinogenic, or cancer-causing. The number of chemical substances or compounds that are known or proven human carcinogens is relatively small, fewer than 100. The list of suspected carcinogens, however, is much larger, about 300–5,000. Substances are evaluated for their potential to cause cancer in two ways: carcinogenesis bioassay studies and epidemiological studies.

Carcinogenesis bioassay is a type of toxicological study in which laboratory animals are exposed to high doses of the substance being evaluated. The

animals then are examined to see whether a malignant neoplasm (cancer) has developed. Exposure takes place over the course of the animal's lifetime (for rats, about 24–30 months). If a cancer develops, toxicological models can be used to predict or estimate the incidence of cancer that may occur when people are exposed to much lower doses of the substance that are more likely to be present in the environment or workplace.

Two categories of toxicological models are used to assess the potential carcinogenicity of substances. A nonthreshold, or one-hit, model assumes that

Category	Name	Health Effect	Sources
Semivolatile organic compounds (cond)	Pentachlorophenol	Damage to kidney or liver; increased risk of cancer	Discharges from wood preserving facilities
	Naphthalene	Anemia, kidney damage, and, in infants, brain damage	Burning of coal and oil, discharges from coal tar production and wood preserving
	Chrysene	Skin damage and possible increased risk of cancer	Found in coal tar pitch used to join electrical parts, also in creosote, a chemical used to preserve wood
Pesticides and herbicides	Chlordane	Liver or central nervous system damage; increased risk of cancer	Residues of banned insecticide
	Dalapon	Kidney damage	Runoff from herbicide used on road rights-of-way
	Heptachlor	Liver damage; increased risk of cancer	Residue of banned insecticide
	1,1-dibromo-3 chloro-propane (DBCP)	Damage to reproductive system; increased risk of cancer	Runoff or leaching from soil where it was used as a fumigant (disinfectant or pesticide) for such crops as soybeans and cotton
	2,4,5-TP Silvex	Liver damage	Residue of banned herbicide
Others	Nitrate	“Blue baby syndrome” in infants less than six months; asphyxiation as nitrate replaces oxygen-carrying hemoglobin in bloodstream	Runoff from fertilizer or leaching from septic tanks into water supply
	Polychlorinated biphenols (PCBs)	Immune, central nervous system, and reproductive damage; Increased risk of cancer	Burning of hydraulic oils and electrical insulating fluids; discharges from waste incinerators
	Radionuclides (uranium, radium, etc.)	Increased risk of cancer	Residues from mining and manufacturing operations; erosion of natural deposits
	Microorganisms ( <i>Giardia lamblia</i> , coliforms)	Gastroenteric disease (diarrhea, vomiting, etc.)	Human and animal fecal waste

very small quantities (the “one molecule” threshold) of a substance can result in cancer. The second type is called a threshold model and assumes that repeated exposures to a chemical are needed before a threshold dose, or minimal amount, is reached and cancer results. Most regulatory agencies generally use the more conservative nonthreshold models for carcinogenesis bioassays. These types of models assign a higher estimate of cancer potency to a chemical or substance than a threshold model. Threshold models often are used in the assessment of noncarcinogenic effects.

There are a number of agencies and research organizations that evaluate chemicals and other substances for their potential carcinogenic effects. Generally, a substance is considered carcinogenic if:

- It has been declared carcinogenic by the International Agency for Research on Cancer (IARC),
- It is listed in the Annual Report on Carcinogens published by the National Toxicology Program (NTP),

### VARIATION IN RATINGS BY DIFFERENT AGENCIES FOR SEVERAL SUBSTANCES

Substance	OSHA	IARC	NTP
Alcoholic beverages	—	1	1
Asbestos	1	1	1
Benzene	1	1	1
Coffee	—	2	—
1,2-Dibromo-3-chloropropane	1	2	2
Cadmium	1	1	1
Chlordane	—	3	—
DDT	—	2	2
Engine exhaust—gasoline	—	3	—
Lead and lead compounds (inorganic)	—	3	—
n-Nitrosodimethylamine (rocket fuel and industrial by-product chemical)	1	2	2
PCBs	—	2	2
Radon (and decay products)	—	1	1
Salted fish (Chinese style)	—	1	—
Solar radiation (sunlight)	—	1	—
Tetrachloroethene	—	2	2
Tobacco smoke and tobacco products	—	1	1
Welding fumes	—	2	—
Wood dust (certain hardwoods)	—	1	—

#### Key:

1: Known human carcinogen; 2: probable human carcinogen; 3: suspected human carcinogen; 4: unknown or unclassifiable human carcinogen; 5: Noncarcinogenic

— Not studied

OSHA: Occupational Safety and Health Administration, U.S. Department of Labor

IARC: United Nations International Agency for Research on Cancer

NTP: National Toxicology Program, U.S. Department of Health and Human Services, Public Health Service

- It is regulated as a carcinogen by the Occupational Safety and Health Administration (OSHA), or
- It is regulated by USEPA as a human carcinogen.

The classification schemes for each of these agencies contain five basic categories:

- The substance is known to cause cancer in people (known human carcinogen).
- The substance is likely to be carcinogenic (probable human carcinogen).
- The substance may cause cancer (suspected human carcinogen).
- Not enough information is available as to whether the substance is carcinogenic (unknown or unclassifiable human carcinogen).
- The substance probably does not cause cancer (noncarcinogenic).

Each classification carries its own set of requirements, and the descriptors are used carefully by researchers and regulatory agencies to describe the substance. Each of these agencies or organizations has its own standards and research practices, so not all substances are classified the same way. The following table provides an example of some substances that EPA considers carcinogenic, and the NTP, IARC, and OSHA do not.

However, for most common environmental contaminants (benzene from petroleum hydrocarbons, for example) there is general agreement as to carcinogenic classification.

# U

**underground storage tank (UST)** An underground storage tank is a metal or fiberglass tank used for bulk storage of liquids under the ground surface. USTs are used for gasoline, heating oil, and liquid chemicals such as benzene, methyl tert-butylether (MTBE), xylene, ethylbenzene, and other volatile organic compounds (VOCs). Among the main sources of residential point source pollution are leaky underground storage tanks. Buried commercial and home heating fuel tanks, as well as retail gasoline tanks, have historically been made of steel. With groundwater acting on the exterior of these tanks and long-term accumulations of water from the fuel on the bottom of the tank (water is denser than fuel), over time, rust produces leaks in the bottom of the tanks. Fuel constantly leaks from the tank at different rates throughout the year (faster rates when it is full) and infiltrates the soil. It percolates through the soil and settles on the surface of the water table, where it floats and accumulates. Depending upon the movement of groundwater, the spilled fuel may either accumulate underneath the tank or move in a plume away from the tank. Either way, both the soil and groundwater become polluted by the leak. In some cases, the plume may reach other houses, where odors may enter the indoor air through the basement. The plume may also enter surface waters if the groundwater intersects a stream, spring, or lake and be spread even farther.

## **TREATMENT OF A LEAKY UST**

The first step in the treatment of a fuel oil leak is delineation of its extent. Samples of soil around the tank are collected using an auger or drill rig and analyzed for heating fuel content. If the leak

has entered the water table, groundwater samples must also be collected and analyzed. Test wells must be drilled around the tank to determine the aerial extent of the plume, as well as the concentration of product or pollutant within the plume. Environmental consulting companies perform these services and must be licensed by the state and local regulatory agencies to perform such work. Ultimately, a map of the plume of pollution that shows both extent and distribution of pollutant concentrations is produced.

## **Residential Tanks**

Remediation of the spill may take on a number of forms depending upon the severity and the extent of affected area. In any event, the tank (UST) must be removed from the ground and disposed of (termed tank pull). For small leaks, some of the soil beneath the ground may require removal but no other procedures. In cases of strong impact on the water table, recovery wells are installed and the fuel oil is removed by pumping. In other cases, soil may be removed and carted away or washed on-site and returned as fill. At times, air may be pumped into the soil, and the fuel is evaporated, or bacteria may be introduced for bioremediation. The method of remediation depends upon the depth of the water table; the distance to surface water and producing water wells; the character of the soil, sediment, or bedrock containing the plume; and the character of the homes and buildings in the area and their distance from the plume.

Even if residential USTs are sound, if the fuel system is changed to gas or electric or if a new tank is installed inside the house, the UST should be removed or treated. If the old tank rusts, it may collapse beneath a person's weight, posing a hazard

or even just collapse on its own, producing a sink-hole. Removal and fill of the hole can be performed relatively cheaply without involvement of regulatory agencies in most states. Treatment usually involves complete drainage and cleaning of the UST followed by filling with sand.

### Gasoline Tanks

Home heating oil tanks are not the only USTs of concern. In gas stations, underground tanks contain the fuel that is pumped into vehicles. They may also leak, creating much larger and more dangerous plumes than from residential tanks. Pipes from the tank to the filler or to the pump may also leak, creating other outlets for spills. Because so much product is involved with gasoline tank leaks and because gasoline flows more easily and may contain harmful additives, remediation of these problems is much more complicated and may require monitoring for long periods after the main cleanup. Pollution from leaking gas station tanks is commonly the environmental problem of greatest concern in residential towns with no major industry. It can affect large parts of communities and produce huge and expensive lawsuits. Leaking USTs from industrial plants are even more of a threat and can cause even greater damage. If other stored pollutants are denser than

water, they may sink through the groundwater system and require much more work for remediation.

The federal government and most state environmental agencies have adopted regulations requiring the upgrades or replacement of these USTs since 1988. Several of these upgrades include secondary containment of both the UST and the accompanying piping; alarm systems, which detect a leak in the annular space between the double walls of secondary containment tanks; and several other methods, including manually using record keeping methods. These leak detection methods have minimized the potential for releases in both commercial heating oil and retail gasoline tanks. Typically, professionals must be licensed for tank closure in many states.

### Industrial Tanks

Heavy industry and the military also use USTs in some applications. Fuels and chemicals may be stored in very large steel tanks that are underground. These may be used at oil refineries in some cases, although most storage is handled in large circular aboveground tanks in these applications. Chemical plants commonly have some underground storage either for the raw materials or for the finished products depending upon the chemical. Currently, these tanks are well monitored and rarely leak, though the

Underground storage tank removal and replacement at a gas station in Sacramento, California, 2003 (AP Images)

**Block diagram of a leaking underground storage tank (UST) for gasoline beneath a gas station and the plume of pollutant in the groundwater**

pipes that fill or drain them may leak on occasion. Military bases have similar uses for USTs, though they may also contain weapons or weapon components in some cases.

If a large UST leaks, it is a major incident. Old leaky industrial USTs wind up as Superfund sites in many cases. The procedure for addressing such a problem is similar to that for a gasoline tank: delineation followed by remediation. The scale of the project is much larger and more involved. It is also more expensive. Some chemicals may be dense nonaqueous-phase liquids (DNAPLs), which, unlike gasoline, sink through the groundwater system. Cleanup of these sites may require extensive removal of soil and a much more complicated remediation plan. In some cases, if the leaking chemicals are toxic or caustic, the project may be very big and require special handling. These are even more expensive.

**United Chrome Products Corvallis, Oregon (1983–present) Soil and Water Pollution** The city of Corvallis, Oregon, is approximately 85 miles (186.8 km) south of Portland. The municipal airport is five miles (8 km) south of downtown and was a military base until it was turned over to the city shortly after the end of World War II. Corvallis developed the airport into a fully self-sustaining entity through revenues from landing fees, hangar rentals, and even sales of grass seed from unused adjoining land. One of the main reasons for its success is the industrial and commercial development that has taken place around the airport. The city of Corvallis owns much of the land and leases it to a variety of private companies. This arrangement creates jobs for the community and provides revenues to the city from land and building rental fees. There are, however, risks associated with being a landlord, especially when one of the tenants is in the chrome electroplating business.

### BACKGROUND

*Chrome* is short for *chromium*, a metal that is used as a coating to add a bright, durable finish to a metal product. This coating can range from 10  $\mu\text{m}$  thick for decorative objects, sometimes called nickel-chrome, such as chair frames or motorcycle handlebars, to coatings up to 1,000  $\mu\text{m}$  thick, described as hard chrome, or engineered chrome, for industrial, wear-resistant applications such as motor valves or pump impellers. Engineered chrome usually is applied to hardened steel products and does not have a reflective finish.

The object to be plated in chrome is first polished, buffed, washed, and finally rinsed with a dilute acid to remove any residual oil or dirt. It is then dipped into a solution of nickel dissolved in hot sulfuric acid at 113–140°F (45–60°C), and an electrical current of 1.5–3 kiloamps per square yard (1.3–2.5  $\text{kA}/\text{m}^2$ ) is passed through the solution. The current causes the nickel to bond to the object. It is this first coating of nickel that provides most of the corrosion protection and metallic sheen for which chrome is famous. The entire process is repeated, and in the last step, the object is dipped into a bath of liquid hexavalent chromium ( $\text{Cr}^{6+}$ ). The chrome imparts a bluish hue or brightness to the item, prevents the nickel from tarnishing, and protects against scratching. Once plating is com-

pleted, the object is dried and rinsed to remove residual acids.

Electroplating is not an environmentally friendly process. Large amounts of spent acid and rinse water containing dissolved hexavalent chromium, nickel, and other toxic metals are generated. The proper disposal of this waste material represents a significant logistical and financial challenge for most electroplating companies, which tend to be relatively small operations. When the U.S. Environmental Protection Agency (EPA) began to develop the nation's hazardous waste management policy, electroplating residues were among the first industrial wastes for which they issued regulations.

### POLLUTION OF THE SITE

In 1956, United Chrome Products (UCP) moved onto a 2.5-acre (1-ha) parcel of land owned by the city of Corvallis in the Airport Industrial Research Park. For the next 19 years, UCP engaged in electroplating operations for a variety of commercial and industrial clients. UCP disposed of its spent plating bath solutions, stripping and cleaning bath solutions, and sludge from the bottom of plating baths by either dumping them into a dry well or storing them in the plating tanks.

The dry well was a three-foot (1-m-) deep pit outside the building and was backfilled with sand and gravel. It was connected to a sump within the building that drained spilled liquids, floor wash water, and product rinsate. Although UCP treated these wastewaters to neutralize the pH, they still contained significant concentrations of dissolved metals. Plating tanks leaked and discharged their contents, and these liquids infiltrated the building's floor and concentrated in soil underneath and adjacent to the structure. The amount of wastewater that flowed into the sump and then to the drywell, or that leaked from the plating tanks, is not known. Facility operators estimated that it was probably about 1,000 gallons (3,785 L) per year. Reportedly, the use of the sump and dry well was discontinued in 1975.

As regulatory pressure on the electroplating industry grew, facilities like UCP were inspected and required to account for their handling of wastes. At the beginning of 1983, the Oregon Department of Environmental Quality (ODEQ) sampled soil and surface water runoff at the UCP site as well as sediment and surface water in the Booneville Slough, a nearby tributary of the Willamette River. Elevated levels of chromium and other metals were detected, and, in July 1983, ODEQ issued a notice of violation to UCP for unlawful disposal of hazardous wastes and the discharge of hazardous wastes into public

waters. Chromium had migrated into the sediment and surface water of Booneville Slough by overland flow across contaminated site soils and via groundwater seepage from the dry well. Other studies showed that surface water contamination extended some two miles (3.2 km) downstream of the facility, and sediments were also affected along a 1.5-mile (2.4-km) stretch of Booneville Slough.

Later that year, the EPA announced that it had completed a groundwater investigation at the UCP site and found that significant levels of chromium were present in both shallow and deep groundwater underlying the property. Area residents tap the deep aquifer for drinking water. Potable water for the airport and associated industrial park is provided by two deep production wells operated by the city, about 3,000 feet (914.4 km) northeast and downgradient of the UCP site.

Chromium concentrations detected in shallow groundwater ranged from a few hundred parts per million (ppm) to more than 1 percent. In the deeper aquifer, chromium levels generally were 10 times lower, but still well above the drinking water quality standard of 0.05 ppm. The EPA estimated that more than 2 million gallons (7.6 million L) of groundwater had been contaminated as a result of UCP's waste management practices. Some 40,000 people resided within a three-mile (4.8-km) radius of UCP, and the nearest families lived approximately 900 feet (274 m) northeast of the facility.

UCP tried to respond to some of the requirements placed on it by both EPA and ODEQ. They emptied sludge from the plating tanks and stored it in drums, eventually disposing of some of them at an approved off-site facility. UCP retained a consultant to develop new waste management procedures and to design upgrades to its plating waste containment system. The environmental actions and required equipment upgrades, however, were too much of a financial burden for the company, and, in November 1984, UCP announced that it would cease operations in early 1985. By May of that year, its surplus equipment had been auctioned off and the building was vacated. Although it had not declared bankruptcy, the owners and operators of UCP simply abandoned the environmental mess they had created over more than 30 years of operation.

### THE CLEANUP

UCP was added to the National Priorities List as a Superfund site on September 21, 1984, and the EPA took immediate steps to stabilize the site. Some 6,300 gallons (23,846 L) of spent plating solution was removed from the site, and more than 100

drums of sludge were shipped to an off-site disposal facility. A chain-link fence was installed to reduce the likelihood of vandalism, and a drainage ditch was rerouted to prevent the flow of contaminated water into nearby surface water channels.

Even after these interim actions were completed, large amounts of chromium remained in on-site soil and dissolved in the groundwater. The EPA and ODEQ turned their attention to the city of Corvallis, the owners of the property, as the entity now responsible for completing the cleanup of the site.

By 1986, the EPA had developed a long-term remedial solution for the site, which was primarily the installation of a groundwater recovery and treatment system. In addition, the building was to be demolished and soil containing elevated levels of chromium that were acting as a continuing source of groundwater contamination was to be excavated for off-site disposal. By 1988, these actions had been completed and levels of chromium in groundwater began to decrease significantly. In 1992, the city of Corvallis assumed responsibility for the operation of the groundwater recovery and treatment system and agreed to reimburse the EPA for some of the costs associated with site cleanup.

Two additional areas of elevated chromium were discovered in 1998, and the city removed almost 2,000 tons (1,814 metric tons) of contaminated soil in 2000 and disposed of it off-site. Groundwater monitoring is ongoing, and chromium levels continue to drop in the shallow aquifer.

Every five years, the EPA evaluates the effectiveness of the work it has completed at the nation's active Superfund sites. These reviews are done to ensure that cleanup objectives are being met and that human health and the environment are protected as the remedial plans are implemented. The review of UCP verified that the cleanup is being successfully executed and is generally on schedule, although yet another small area of chromium-contaminated soil that will need to be addressed has been discovered between two monitoring wells on the site. The city of Corvallis has included the UCP property in the airport's master plan, and the site is being considered for redevelopment as a fuel storage depot.

**urban air pollution** Beginning around 5000 B.C.E., agricultural techniques became sophisticated enough for farmers to produce more food than they needed. This new era heralded a set of far-reaching changes to human culture, allowing the development of mercantile, ruling, and military classes. Not everyone needed to tend crops or hunt to survive. These changes led to the domestication of animals, storage of surplus food, and concentration of populations in central locations or cities (from the Latin root *civis*, meaning "citizen") to trade and have access to the food. The formation of cities also spurred the development of educational and philosophical systems, medicine and technology, and political processes. People with many backgrounds joined to share ideas and skills and then take them to other areas.

Although human activities have always affected their environment, these changes could be accommodated when populations were small and widely dispersed. Tribes or family groups of up to a few hundred people living in semipermanent seasonal settlements or campsites may have overexploited nearby plants and animals through intensive hunter-gatherer activities, but local ecologies rebounded fairly quickly when the humans moved on.

As populations amassed in cities, however, the air, water, and soil they depended upon began to deteriorate. By about 10,000 years ago, scientists estimate that the Earth's population was between 1 million and 10 million people. By 1 C.E., the world population had grown to between 140 million and 170 million people, and ecosystems were struggling to compensate for the increasingly aggressive use of natural resources. In ancient Rome (100 C.E.),

which had an estimated population of more than 1 million permanent residents, prominent politicians and poets (e.g., Seneca and Horace) regularly complained about the foul smell and color of the city's air, naming it *gravioris caeli* (heavy heaven) or *infamis aer* (infamous air). Trash, sewage, and industrial wastes from mineral processing or leather tanning regularly fouled Rome's local streams and drinking water supplies. In medieval England, when the queen arrived in Nottingham in 1257, the smoke from coal burning had so polluted the air that, afraid for her health, she left after only a brief visit. Air quality in London eventually became so intolerable that King Edward I tried to ban the burning of coal threatening, "whosoever shall be found guilty of burning coal shall suffer the loss of his head"—and this was 500 years before the Industrial Revolution!

Today, as the result of modern technology and effectively enforced environmental regulations, most

## TOP 25 MEGACITIES RANKED BY TOTAL POPULATION

No.	Megacity (including surrounding metropolitan areas)	Population (millions)	Location
1.	Tokyo	34.3	Japan
2	Guangzhou	24.2	China
3	Seoul	24.2	South Korea
4	Mexico City	23.4	Mexico
5	Delhi	23.2	India
6	Mumbai (formerly Bombay)	22.8	India
7	New York City	22.2	United States
8	Sao Paulo	20.9	Brazil
9	Manila	19.6	Philippines
10	Shanghai	18.4	China
11	Los Angeles, California	18.0	United States
12	Osaka	16.8	Japan
13	Kolkata (formerly Calcutta)	16.3	India
14	Karachi	16.2	Pakistan
15	Jakarta	15.4	Indonesia
16	Cairo	15.2	Egypt
17	Moscow	13.6	Russia
18	Beijing	13.5	China
19	Dhaka	13.4	Bangladesh
20	Buenos Aires	13.3	Argentina
21	Istanbul	12.8	Turkey
22	Tehran	12.7	Iran
23	Rio de Janeiro	12.6	Brazil
24	London	12.4	United Kingdom
25	Lagos	11.8	Nigeria

people living in the United States and other developed countries can breathe the air without fear. This, however, is not true for millions of people living in many cities in other parts of the world. The poor air quality in those cities is tied directly to the size of the population, the rate and type of economic development taking place, and, to a lesser extent, local geography and climate.

### MEGACITIES AND ENVIRONMENTAL QUALITY

There are many social, cultural, and economic advantages to cities, but above a certain size, they become very difficult to sustain ecologically. The industrial and commercial activities that take place in a city, as well as the people who live there, consume enormous amounts of resources. In addition, the wastes from the processing and consumption of

these resources must be removed and managed in a way that does not foul the environment. Infrastructures and systems have been developed over time that generally are effective in making most cities, for the majority of people in developed countries, reasonably pleasant and healthy places to live. Clean water is piped directly to homes, garbage is removed regularly, subways and buses reduce traffic congestion, and industrial polluters are well regulated.

Developed countries are those that have a high Human Development Index (HDI). As defined by the United Nations, the HDI is a comparative measure of life quality, especially for children, in five major categories: poverty, education, literacy, child mortality rates, and life expectancy. A country with a high HDI almost always has a large per capita gross domestic product, a representative government, an open or free-market economy, and a strong anti-corruption culture. A country with an HDI of 0.8 or more is considered developed (e.g., United States and most of Western Europe), whereas those with HDIs between 0.5 and 0.8 are designated as “moderately developed” (some of the former Soviet Union Eastern Bloc states). Countries with an HDI below 0.5 are classified as “developing” (many African nations).

As cities become larger, especially in developing countries, much of the infrastructure needed to make them sustainable, or even livable, has not kept pace with their growth. This is readily apparent in the world’s megacities—those with more than 10 million people living at a density of at least 3,220 people per square mile (2,000 people/km<sup>2</sup>). The world’s first megacity was formed in 1950 and consisted of the New York City metropolitan area. By 2006, 23 megacities had developed, reflecting a trend away from rural life to urbanization not only in North America and Western Europe, but also in all the major countries of the world. The table on page 744 lists the megacities in the year 2007.

Metropolitan areas that are likely to become megacities by 2015 include Jakarta (Indonesia), Osaka (Japan), Tianjin (China), Bangkok (Thailand), and Manila (Philippines). Occupying less than 5 percent of the Earth’s surface, the existing megacities use more than 70 percent of the planet’s wood and 50 percent of the water and generate more than 80 percent of all anthropogenic atmospheric carbon. Thirty-six megacities are expected to have formed by 2025.

The overwhelming size of megacities often makes them difficult to manage in an environmentally effective manner, especially in terms of air pollution. Water contaminated by sanitary or industrial wastes can be contained, treated, and either recycled or discharged by using well-defined and controlled processes. Simi-

larly, solid wastes can be collected and disposed of in a manner that is reasonably efficient and fairly protective of public health. Air pollution, however, especially from nonpoint sources, is much more difficult to control because of its enormous volume, tendency to move quickly away from its point of origin (often across national boundaries), and the immediate effect that attempting to control or reduce it has on the general population of a megacity. One study by the United Nations found that in cities with populations of greater than 9 million people, health risks to children related to air pollution (asthma, bronchitis, etc.) are greater than if those same children live in less congested towns and villages.

It is tempting to point to megacities in developing countries as those with the worst air quality. Although it is true in many cases (as described in the case studies that follow), it is not universally applicable. New York, Paris, Tokyo, and Los Angeles have some of the highest nitric oxide levels (produced by automobile emissions) in the world. The main difference in air pollution found in developed versus developing countries is the reaction of both the government and population to bad air quality when it is detected and reported. In most developed countries, strict regulatory programs are established to reduce atmospheric contaminant loading and require the installation of pollution control equipment. This is often not the case in developing countries, or, if such requirements are in place, they may be enforced only selectively or sporadically.

## URBAN AIR QUALITY: CASE STUDIES

A review of air quality in the four urban areas describes the reasons for such poor conditions and tries to define the cultural and institutional challenges faced by each megacity in attempting to develop and implement sustainable air quality improvements. All the case studies are focused on megacities in developing countries because these often contain the largest populations that are being the most severely impacted.

### Mexico City, Mexico

Between 1970 and 2000, the Mexican economy grew more than 200 percent, resulting in better education, medical care, and social services for many of its citizens. In 2003, Mexico had a UN calculated HDI of 0.813, categorizing it as a developed country. Much of this growth has been centered in Mexico City, whose population increased from 9 million people in 1970 to more than 20 million by 2000. As Mexico’s capital and only megacity, Mexico City also has a reputation for having some of

the poorest air quality in the Western Hemisphere. Founded in the 1520s, Mexico City is in a large valley surrounded by volcanic peaks in the center of the country's *altiplano*, or "high plane," a plateau elevated about 7,500 feet (2.3 km) above sea level. This geography plays a crucial role in exacerbating air pollution in Mexico City. In 1940, average visibility in Mexico City was more than five miles (8 km). The snow-capped peaks of the surrounding volcanoes towered over the city and added a picturesque charm and majesty that were not found in many other capital cities. Today, visibility is often less than one mile (1.6 km), and the mountains to the east, south, and west are seldom seen. The mountains that surround the city prevent winds from helping to sweep away contaminants and help trap hydrocarbons and the by-products of fossil fuel combustion: particulate as well as sulfur and nitrogen oxides. Contributing to pollutant enrichment of Mexico City air quality are winter temperature inversions, when a layer of warmer air moves over, or caps, a layer of underlying colder air.

In 2001, Mexico was the 13th largest emitter of carbon dioxide (CO<sub>2</sub>) in the world, discharging about 106 million tons (96 million metric tons) of this greenhouse gas. Of all CO<sub>2</sub> emissions in Mexico, 13 percent were released in Mexico City. Particulate pollution (microscopic size pieces of soot and ash produced primarily by the combustion of diesel fuel) exceeds international air quality standards (i.e., safety level) almost once per week. Ground-level ozone concentrations, produced when sunlight interacts with nitrogen oxides and volatile organic compounds, are above international air quality standards 330 days of every year. Nitrogen oxides reach unhealthy levels about 180 days a year.

More than 80 percent of the air pollution within Mexico City is directly connected to automobile emissions. Mexico City has slightly fewer cars than Los Angeles (4 million v. 5.2 million), but they are older, do not have catalytic converters, are in poorer condition, and burn gasoline or diesel fuel less efficiently. They consume some 10 million gallons (37.9 million L) of fuel daily and use more polluting fuels (those with high sulfur levels). The four major pollutants present in Mexico City's air are ozone (O<sub>3</sub>), sulfur dioxide (SO<sub>2</sub>), nitrogen oxide (NO<sub>x</sub>), and carbon monoxide (CO). Each of these originates from the incomplete combustion of gasoline or diesel fuel. More than 36,000 factories also contribute to the often-unhealthy levels of these air pollutants.

Mexico City's air contains dried fecal matter present in sewage discharged into open air lagoons near the city as well as from the millions of stray dogs that roam the streets. Physicians practicing in Mexico City have documented cases of hepatitis, dysentery, and other gastrointestinal diseases that resulted from breathing airborne fecal matter. Every year 4,000 premature deaths that are attributed to air pollution occur in Mexico City, and 2.5 million days are lost from work.

Mexico's government is working hard to improve air quality not only in Mexico City, but also in the six other largest urban areas: Guadalajara, Mexicali, Monterrey, Tijuana-Rosario, Toluca, and Ciudad Juarez. Since 2000, Mexico has spent more than \$5 billion on technology initiatives and regulatory programs to try to clean the air in its capital. These have included the following:

- replacing municipal buses that ran on diesel fuel with hybrid motors (gasoline-electric or natural gas) and requiring the installation of particulate filters and high-efficiency catalytic converters on certain types of diesel engine vehicles
- requiring that owners of private cars either have a catalytic converter or refrain from driving one day per week. During air pollution emergency days, vehicles ending with either an odd or even license plate number (depending upon the day) are allowed on the road
- shutting a local oil refinery that could not meet stringent air emission standards now in effect for the city
- replanting trees and other vegetation on nearby hills and mountains that had been clear-cut years before

Tougher, more expensive, and politically sensitive reforms have proven difficult to implement and enforce. This problem may be related to the way oil and natural gas are managed in Mexico. In 1938, the assets of two foreign-owned oil companies, which had been developing Mexico's oil resources for more than 20 years, were nationalized by the Mexican government. The result, PEMEX or *Petróleos Mexicanos*, is the world's fourth largest oil exporter. PEMEX is the only company allowed to extract,

refine, and sell petroleum fuels in Mexico. Its current reserves, located primarily offshore in the deep waters of the Gulf of Mexico, are estimated by the company to be in excess of 200 million barrels (31.8 billion L). For comparison's sake, Kuwait estimates oil reserves of 100 billion barrels (1.59 trillion L). While seemingly small compared to the oil reserves in the Middle East, PEMEX's potential oil is very attractive because of its presence in relation to markets in the United States. Currently, PEMEX provides revenues that make up a third of the Mexican government's annual operating budget.

The key to reducing air pollution in Mexico City is controlling emissions from mobile sources. The Mexican government has provided incentives for its citizens and some businesses to retire older vehicles and replace them with cleaner, more fuel-efficient cars and trucks. The quality of the gasoline and diesel fuel that runs those vehicles plays a major role in citywide air quality. Very low-sulfur fuels, both gasoline and diesel, are needed to achieve real gains in Mexico City air quality. To remove the sulfur, PEMEX's nine refineries need expensive upgrades to their processing equipment, costing between \$2 billion and \$4 billion, which could significantly affect the company's revenue contribution to the government.

Although considered a developed country, Mexico is still struggling with balancing economic progress against environmental quality. The signs are favorable that a viable solution is forthcoming. Mexico's federal environmental agency, Secretaría del Medio Ambiente, Recursos Naturales y Pesca (SEMARNAP—Secretary of the Environment, Natural Resources, and Fishery), and Mexico City's local Secretariat of the Environment have established air quality standards that are just as strict as those of the United States. PEMEX has been working to produce low-sulfur fuel by 2008, and alternate sources of electricity, such as hydroelectricity, geothermal, solar, and wind, are being actively developed. In fact, Mexico is the third largest producer of geothermal power (almost 900 megawatts of capacity), ranking just behind the United States and the Philippines. This is reflected in its greenhouse gas emissions, which have remained fairly constant since the late 1990s.

Mexico City's air quality is improving, although it will be years before its residents can regularly breathe healthy air. With an increasing commitment to enforce existing laws, however, and continued development of innovative air pollution control systems and technologies and use of alternative energy sources, Mexico and Mexico City are on the verge of reversing years of disregard for the environment.

### Delhi, India

If Mexico City is beginning to emerge from its environmental dark ages, New Delhi, India, is at the beginning of its journey. India, a country that is rapidly becoming a global economic powerhouse, also has some of the most polluted cities in the world, and New Delhi is a microcosm of all the ecological challenges that this rapidly developing country faces.

The world's second most populous country after China, India (HDI = 0.602) hosts almost 17 percent of the planet's population (1.1 billion in 2001) on only about 2.5 percent of its surface area (135 million square miles [349.7 million km<sup>2</sup>], about one-third the size of the United States). In 1991, India began to implement a series of economic and political reforms that transformed the country. Import tariffs were reduced, foreign investment and ownership of local business encouraged, and government regulation or management of many industries (including telecommunications) ended. Since these reforms took effect, India has become one of the 10 fastest developing countries, with its gross domestic product increasing at an annual rate of 6 percent. With this newly earned prosperity, India's population growth has slowed, literacy rates have increased (to 54 percent in 2001), and a spirit of entrepreneurship is sweeping the country. Poverty rates dropped from 40 percent in 1994 to 25 percent in 2000. Environmental problems, particularly air pollution, combined with the government's inability to provide such basic services as clean water, health care, and education, serve as a drag on further development and prevent India from assuming a true leadership role in Asia.

If there is one place in India where economic prosperity is juxtaposed with poor environmental quality, it is in the country's capital city, Delhi. As India's third largest city—only Mumbai and Kolkata have more people—Delhi is actually made up of two cities: Old Delhi to the north, formerly the capital of Muslim India, and New Delhi to the south, declared capital of the country by the British in 1911.

A tributary of the Ganges Yamuna River makes up the eastern boundary of the 600-square-mile (1,554-km<sup>2</sup>-) Delhi metropolitan area and the Thar Desert lies to the west. Hot, flat-lying plains are to the south and a cooler, hilly region to the north and east. The average annual temperature is 77°F (25°C), and the climate is semiarid, with most of the rain (around 30 inches [78 cm]) falling during the monsoon season: June through October. These rains act as effective scrubbers, removing both suspended particulate from desert dust storms (called *Andhis*) as well as industrial air pollution. Pre- and post-

monsoon calms, combined with regular midwinter temperature inversions, lead to increased pollutant loading as contaminant concentrations build up in the stagnant air.

Two national laws codify the standards for air quality in India: the Air (Prevention and Control of Pollution) Act, passed in 1981, and the Environment (Protection) Act, promulgated in 1986 shortly after the Bhopal disaster. The standards established by these acts for lead, suspended particulate matter, SO<sub>x</sub>, and NO<sub>x</sub> are similar to those in the United States and the European Union. But the Central Pollution Control Board (India's equivalent of the U.S. Environmental Protection Agency [EPA]) does not have a good record of uniformly or vigorously enforcing these standards throughout the country.

The 20 million inhabitants of Delhi use almost 5 million vehicles to travel into, out of, and around the city. About two-thirds of these vehicles are small motorcycles or rickshaws powered with noisy two-stroke engines. These types of engines are small, lightweight, inexpensive, and powerful. In two-stroke engines, oil (for lubrication) is premixed with the gasoline, and unburned oily residues are pushed out the exhaust chamber along with the regular by-products of combustion (NO<sub>x</sub>, SO<sub>x</sub>, etc.). For all their advantages, two-stroke engines are environmentally unfriendly, emitting much more contamination than other types of internal combustion engines.

Delhi's system of old, twisting, and tortuous roads intermixed with more modern streets and highways creates low-speed driving conditions that result in poor engine performance and additional air pollution. Even though the city has expanded its mass transport facilities (primarily buses with coordinated rail service), enormous, long-lasting traffic jams are still commonplace.

Total suspended particulate matter (SPM) is Delhi's most obvious air pollution problem. SPM in Delhi's air annually averages 370–450 mcg/m<sup>3</sup>, well above the prescribed standard of 140–360 mcg/m<sup>3</sup> (depending upon local land use). SO<sub>x</sub> and NO<sub>x</sub> levels are slightly below national standards, but they have increased by almost 100 percent since the late 1990s, and this trend of deteriorating quality is likely to continue. Underlying these findings is a concern that Delhi's air quality data are not collected or analyzed consistently or in a scientifically appropriate manner, either because of poor training of the technicians or lack of funding for needed equipment. The human health consequences of this pollution are disturbing. Approximately 7,500 premature deaths and almost 3 million hospital admissions or severe illnesses that require medical treatment are attributed to exposure to air pollution.

Although cars and other motor vehicles are responsible for 67 percent of the 3,300 tons (2,994 metric tons) of pollutants that are emitted every day into the air over Delhi, the following other sources also are present:

*Coal-fired power plants (13 percent).* Over the last 25 years, India's rapidly growing population and increased rate of urbanization have resulted in the doubling of energy consumption. Even with this explosive growth, the country's per capita electrical use still is one of the lowest in the world. India (like the United States) is not a signatory to the Kyoto Protocol (the international agreement to reduce greenhouse gas emissions) and is the fifth largest emitter of CO<sub>2</sub> in the world. The rate of greenhouse gas discharges by Indian business and industry is expected to increase dramatically over the coming years.

The three power plants that provide electricity to Delhi are symptomatic of India's energy crisis. Operated using high-sulfur coal or peat fuels, these power plants emit more than 6,000 tons (5,443 metric tons) of fly ash into the air every day and have only recently installed electrostatic precipitators. In addition, the government is hesitant to enforce national limits on sulfur dioxide and nitrogen oxide emissions, because of the need for electricity to support the current rate of economic growth. Even when limits are established, they are often not locally enforced for that same reason.

*Industrial discharges (12 percent).* Delhi has been India's leading manufacturing and commercial center since the 1800s, specializing in arts and crafts, textiles and handlooms, as well as copper utensils. The air pollution from these and other types of industrial activities has been on the decline since the 1990s, when Delhi began to shift to a service-based economy. Since 1991, more than 1,300 industries that could not meet air pollution control requirements have closed, and this trend is continuing as the Indian government seeks to encourage development by less polluting, less energy-intensive businesses.

*Domestic sources (8 percent).* The primary sources of these emissions are cook stoves called *chulhas* that are fired with biomass fuels such as coal, dung, crop residues, wood, and charcoal. India has embarked on a campaign to encourage the use of natural gas-fired *chulhas*, as well as those that incorporate solar technology.

The residents of Delhi are far from resigned to living with dirty air. They have instituted a series of aggressive air pollution control measures:

- improving the quality of lube oil for small vehicles

- banning the use of leaded gasoline (resulting in a substantial drop in ambient air lead concentrations within the city)
- requiring the use of low-sulfur diesel fuel in buses and trucks
- aggressively checking for fuel adulteration at service stations
- launching a public antipollution campaign designed to encourage the use of mass transit and other air quality improvement measures
- mandatory retirement of vehicles older than 15 years
- gradually switching the entire public transportation system (taxis and buses) to natural gas-fueled engines

Nationally, India is aggressively pursuing alternate energy rather than building conventional fossil fuel- or nuclear-driven power plants. It is the only country that has a government ministry focused exclusively on the development of nonconventional energy sources. In India, solar power and wind power are being touted as the most effective ways to produce electricity for the 70 percent of the population that does not live in cities. Delhi, as have many of India's major cities, has begun to make some progress in its effort to balance economic growth by addressing air pollution and other quality-of-life issues such as health care and education. Its success will lie in developing and maintaining a strong commitment to the promotion (and enforcement, when necessary) of industrial and community compliance with existing environmental regulations.

### **Santiago, Chile**

Santiago, Chile's capital and largest city, started out as a tough industrial town and the manufacturing center of the country. Historically, the development and growth of the city were based primarily on the extraction and refining of copper. Chile, with an HDI of 0.854, is the world's largest producer of refined copper. In the mid-1980s, the industrial character of Santiago began to change, and it has evolved into one of South America's most important financial and commercial centers. This is due largely to the strong growth of the Chilean economy and the country's relative political stability. This growth has been accompanied by environmental problems, and Santiago, although not a megacity, has air quality

so degraded that it is regularly ranked among the world's 20 most polluted urban areas.

Over the past three decades, Santiago's population has more than tripled, growing to 6 million people, about half of the population of the country. It is the sixth largest city in South America and is expanding so fast that the government has instituted several programs to encourage relocation of businesses and people into suburbs and areas away from the central city.

Santiago lies in a beautiful valley of central Chile, between the towering, snow-capped Andes to the east and the lushly vegetated Cordillera de la Costa (mountains of the coast) to the west. The city has a climate characterized by wet winters—June through August, with an average rainfall of 10–13 inches (25–33 cm)—and relatively hot, dry summers—November through March with average temperatures above 90°F (32°C). Both its location in a narrow valley and its seasonal weather patterns—calm, dry summers and regular thermal inversions during the winter—contribute to Santiago's air pollution. The calm air of summer allows pollutants to accumulate over the city between the two mountain ranges, and the winter thermal inversions, despite the occasional rainfall's scrubbing effects, act as a meteorological lid or cover and retard the dispersal of contaminants.

Chile enacted several environmentally related legislative initiatives. In 1990, the National Commission for the Environment (CONOMA) was created to develop and implement national environmental plans. The Special Commission for Decontamination of the Metropolitan Region (CEDRM) also was formed to focus specifically on pollution in Santiago. Regional Environmental Commissions (COREMAs) work throughout the country to improve environmental conditions. Chile is a signatory to several major international environmental conventions.

In the 1990s, the Chilean government recognized that the use of natural gas would both reduce Santiago's air pollution and provide a reliable source of energy. Five pipelines were constructed to import this clean-burning fuel from Argentina and Bolivia for both power production as well as industrial and residential use. The results were almost immediate. Between 1990 and 2000, air pollution in Santiago decreased dramatically as factories and power plants converted to natural gas. The availability of natural gas for use in Chile, however, is dependent on political and economic conditions in Argentina and Bolivia. Coupled with reductions in supply, a pattern of decreasing rainfall and subsequent lower river water levels has forced many of Chile's hydroelectric and natural gas-fired power plants to switch to more

polluting petroleum or coal. The gains realized in the 1990s were lost and Santiago again faces an air pollution crisis, this time from two, more politically difficult to control sources: automobiles and metal refining.

Although Santiago has a fairly extensive and reliable mass transit system that includes five subway lines and a modern bus fleet, as in many urbanized areas, its citizens like the personal freedom and economic flexibility of owning a car. Approximately 1.6 million automobiles operate within Santiago, and they generate about 53 percent of its air pollution. Exhaust from motor vehicles, especially on days when there is little wind or during a temperature inversion, causes concentrations of ground level ozone, total suspended particulate (TSP), and NO<sub>x</sub> and SO<sub>x</sub> to reach dangerously high levels. TSP values are often more elevated as wind blows dust from the numerous unpaved roads that connect Santiago's impoverished suburbs to the city. Adding to the pollutant load are emissions from more than 6,500 industrial (fixed or nonpoint) sources.

Public health has been significantly affected by air pollution in Santiago, with impacts ranging from premature death to increased occurrence of chronic bronchitis, pneumonia, and asthma. Particulate concentrations measured during the winter (July and August) have reached 300 to 400 mcg/m<sup>3</sup>,

well above the World Health Organization guideline 60–90 mcg/m<sup>3</sup>. The table compares atmospheric particulate concentrations measured in Santiago in 1992 with those in other cities around the world.

The Chilean government identified and implemented several short-term solutions to mobile source pollutants:

- An air pollution alert system (based on TSP concentrations) has been developed to warn people of poor air quality. Actions range from suggestions that people avoid strenuous outdoor activity to mandatory school closings and factory shutdowns.
- Depending upon air quality conditions, a rotating schedule restricts the number of cars allowed on the streets, similar to Mexico's odd/even system. Using this system, the government can prevent up to 20 percent of vehicular traffic from operating within the city.
- Many of the city's buses and taxis have been converted to operate on natural gas or hybrid fuel (diesel/electric).

In addition to these changes, road systems are being improved to ease congestion, and the subway system is being expanded to serve outlying areas better. Santiago also requires the use of very low-sulfur diesel fuel and has implemented an aggressive street cleaning program. These changes are making a difference. In 2005, only four emergency air quality alerts and nine "preemergency" notices were issued, as compared to 23 alerts and 157 preemergency notices in 1999.

Even though agriculture, textiles, and leather products are important industries, copper mining and processing from the rich deposits in the Atacama Desert region, 800 miles (1,288 km) north of the city, are the mainstay of Chile's rapidly developing economy. Once the world's largest open-pit copper mine, Chuquicamata (named for the Native Indian people who had worked the copper deposits since pre-Hispanic time) produces about 30 percent of the world's copper—720,000 tons (653,173 metric tons) annually. Associated with the sulfide ores extracted at this and other mines in the area are such air pollutants as arsenic, SO<sub>x</sub> dioxide, and TSP. Most air quality effects of mining occur locally, and fortunately the mines are in a sparsely populated part of the country. Occasionally, weather patterns disperse these pollutants over wide areas. In 1990,

#### COMPARISON OF TOTAL SUSPENDED PARTICULATE (TSP) CONCENTRATIONS

City	Average TSP (mcg/m <sup>3</sup> )
Athens	180
Bangkok	220
Beijing	370
Kolkata	390
Los Angeles	45–115
Manila	120–250
Mexico City	100–500
Mumbai	140
New York	60
Santiago	210
São Paulo	50–85
Tehran	260
Tokyo	50

for example, Chuquicamata was forced to cease operation for a month because excess emissions from its smelter were contributing to air quality problems in Santiago. The numerous other mines operating within the Atacama mining district have similar air quality impacts, both locally and nationally.

Environmental effects of mining are being mitigated in a number of ways. As the government invites more foreign participation, those companies introduce a culture of more strict compliance with local environmental standards. In addition, Chile now requires an environmental impact statement (EIS) before mining operations can begin in an area. This EIS must describe how air, water, soil, and other natural resources will be protected or restored during and after the mining process.

Chile, as have many developing countries, exploited its natural resources in order to join the modern world. This was done without much thought to the environmental consequences of those activities. The challenge for Chile now is to strengthen and secure those economic gains while balancing the need to maintain a sustainable and livable environment for its citizens.

### Linfen City, Peoples Republic of China

China (HDI—0.76) has emerged as an industrial and manufacturing superpower, but this development is stressing its environment to the breaking point. China is the fourth largest country in the world by area, and its world-topping population, more than 1.2 billion people, coupled with a wide variety of plentiful natural resources and an entrepreneurially oriented government, drives an economic engine that is changing the world.

By virtue of its size, China is often easier to view as a continent, rather than a country. In the northern part (Inner Mongolia, Heilongjian Province), the climate is very cold, whereas in the middle and lower reaches of the Yellow River, temperatures moderate (warm summers and cool winters). In the south, climatic conditions range from subtropical (east of Qinghai-Tibet Plateau) to tropical (Guangdong and Yunnan Provinces). At higher elevations, such as the Qinghai-Tibet Region, plateau climatic conditions (hot, dry summers and cold, dry winters) prevail. China is not characterized or dominated by a single topography or landform. Steppes, deserts, and high mountain ranges, including the Himalaya, make up the major surface features in the western part of the China. Large river basins form much of the central interior, and in the east are plains and low hills.

Just as the climate and topography vary, so do China's people and cultures. Nine major ethnic

### CHINA'S TOP EXPORTS (\$ MILLION)

Commodity	\$ millions
Electrical machinery and equipment	55,500
Power generation equipment	52,960
Apparel (clothing)	23,500
Iron and steel	9,200
Furniture	7,800
Medical equipment and optics	7,100
Footwear	7,000
Mineral fuels and oils	6,500
Chemicals	6,200
Plastics	6,000

groups speak eight different languages and have religious practices rooted in Taoism, Buddhism, Christianity, Islam, and Falun Gong. China's industrial focus is equally varied. Its top 10 exports are summarized in the accompanying table.

China began to modernize its economy in 1978 and since then has seen, on average, an annual increase of 8 percent or more in its gross domestic product. The central government has attempted to remain faithful to its underlying communist ideology, but China has established economic and trade zones where Western style capitalism and investment are not only permitted, but actively encouraged. The political and social reforms needed to ensure accountability for environmental quality, however, have not kept pace with economic growth and liberalization policies.

Studies by both the World Bank and the World Health Organization have found that of the 10 most severely air polluted cities in the world (see the following table), six are in China. Linfen City, in Shanxi Province, holds the dubious honor of being the world's most polluted city.

Linfen is one of China's oldest settlements. Located in the southwest of Shanxi Province, about 300 miles (480 km) southwest of Beijing, Linfen is about 8,000 square miles (20,720 km<sup>2</sup>) and has a population of 4 million. For most of its history, Linfen has been an agricultural center, a food exporter especially famous for high-quality fruits. But more recently the city's economic focus has shifted to a new type of export—coal. China is the world's largest coal producer, and Shanxi Province in northern China has more than a third of the country's proven reserves.

Of the nearly 26,000 coal mines in China, 40 percent are in Shanxi Province. Coal production increased from 1.1 billion tons to 1.9 billion tons (1–1.7 billion metric tons) from 2000 to 2005, and the rate of mining is increasing. This strategic area produces 70 percent of China's energy, primarily from coal-fired power plants, and Linfen is at the center of this industry. Straddling the banks of the Fen River valley, Linfen has all of the physiographic characteristics to make it susceptible to air pollution: high valley walls that reduce air mass mixing and a semidry monsoon climate with hot, calm, and dry summers leading to winters dominated by temperature inversions accompanied by the occasional heavy rainfall.

Major air pollution sources are of three types: electrical power generation (60 percent); iron, steel, and mineral production (30 percent); and other sources such as textiles, cement, and households (10 percent). Pollutants are primarily particulates (dust and soot) along with the by-products of combusted coal, the most serious of which is SO<sub>2</sub>. In 2000, air pollution sources in Linfen released about 75,000 tons (68,039 metric tons) of SO<sub>2</sub> and almost 200,000 tons (181,437 metric tons) of particulates from about 500 industrial sources. By 2002, these amounts had increased by approximately 30 percent. The highest pollutant concentrations in Linfen are found in winter, when stagnant air masses combine with high household use of coal to produce a visible haze that often slows traffic and makes outdoor activities unhealthy. Smoke generally blankets the city, and greenery in public streets and backyards is difficult to maintain because of damage from acid rain. Of the estimated 300,000 premature deaths in

China that are attributed annually to air pollution, 100,000 occur in Linfen.

The Chinese government is attempting to manage and control air pollution and environmental degradation in Linfen and other areas around the country. National environmental policies are developed by the State Environmental Protection Administration (SEPA) and approved by the State Council. Established in 1998, SEPA has the mission of promulgating and enforcing national environmental policy and regulations, collecting environmental quality data, and providing technological advice and guidance to policy makers on national and international environmental matters. One major initiative was the 2002 Cleaner Production Promotion Law. This law established special high-priority environmental remedial programs in 10 major cities and river valleys, including Linfen. China's basic air pollution control law—Prevention and Control of Air Pollution—was revised in 2002 to reduce emission limits and toughen penalties for noncompliance.

China faces an additional hurdle in its attempts to improve environmental quality that many developing countries do not. Environmental policies in many countries are formed at the grassroots level by the people whose health or quality of life is most affected by the pollutants being released. Through established political processes, constituent groups put pressure on their government for change. In China, where those types of public advocacy political processes are not well developed, environmental change is slow. While China may be modernizing, it steadfastly holds on to its Communist form of government, which, in turn, tends to make consistent and meaningful implementation of environmental reforms difficult.

**Urquiola oil spill La Coruña, Spain (May 12–25, 1976)** *Water Pollution* Galicia is an autonomous region on the Iberian Peninsula along the west coast of Spain. It is the westernmost point of continental Europe, and its rugged coastline is known by mariners around the world as the Costa del Morte, or coast of death. The perilous jagged cliffs that reach into the sea, combined with fierce shoreward winds and strong currents, have had an average of three shipwrecks per year for at least the last 100 years. This is unfortunate, considering that Galicia also is on one of world's oldest and busiest shipping lanes. Vessels sailing to and from the Persian Gulf, India, and China make their way northward up the west coast of Africa and sail directly past Galicia on their way to ports in mainland Europe on a regular basis.

In contrast to its dangerous maritime reputation, the coastline of Galicia also is well known as one of the most scenic areas in Europe. Tourism is an important component of the region's economy, and the numerous coves and bays provide important wintering habitat for seabirds from throughout the North Atlantic including gannets, guillemots, cormorants, puffins, and gulls. Galicia's offshore waters are well oxygenated and nutrient-rich and support an abundant variety of fish, shellfish, whales, dolphins, and porpoises. As a result, the Galician fishing fleet is the largest in Europe.

### BACKGROUND

The *Urquiola*, a 905-foot- (276-m-) long, 128-foot- (39-m-) wide 59,723 DWT (deadweight tonnage) Panamax crude carrier, was placed into service in 1973. Flying a Spanish flag, the tanker carried oil from the Middle East to refineries in Spain, particularly to the government-operated facility in La Coruña, the second largest city in Galicia, northwestern Spain. La Coruña is one of the busiest ports on the Atlantic coast of Europe. It was the embarkation point for the Spanish Armada in 1588 as it set sail for England and was the site of a key battle between the French and English in the 1809 Napoleonic War. Today, the 260,000 people who live and work in and around its harbor and along its coastlines rely on fishing, farming, ship repairs, and the metal, glass, and ceramic industries for their economic livelihood. Tourism also

plays a major role in the local economy, as the area's picturesque harbor, rugged coastlines, and secluded bays and estuaries attract visitors from all over the world.

On May 12, 1976, the *Urquiola*, loaded with about 111,330 tons (101,000 metric tons [513,000 barrels]) of Kuwaiti crude oil, entered the main shipping channel to La Coruña harbor. This type of oil, also called Arabian light crude, is a medium-weight oil with an American Petroleum Industry (API) gravity of about 33 and a pour point of  $-30^{\circ}\text{F}$  ( $-34.4^{\circ}\text{C}$ ). The pour point of oil is the lowest temperature (in degrees Fahrenheit or degrees Celsius) at which it will flow or behave as a fluid. Oils with high pour points usually contain large amounts of paraffin and require more extensive refining to make them economically attractive. Pour points can range from  $0^{\circ}\text{F}$  ( $32^{\circ}\text{C}$ ) to below  $-70^{\circ}\text{F}$  ( $-57^{\circ}\text{C}$ ).

### THE ACCIDENT AND SPILL

At only three years old and with a good service record, the *Urquiola* approached La Coruña skippered by a Spanish captain in familiar waters. In the early morning light and on the way into the harbor, the tanker scraped its bow along a shoal that reportedly had not been marked on the ship's charts. Oil began to leak from the damaged vessel almost immediately, and, fearing a fire and explosion, as well as an environmental catastrophe, port officials ordered the vessel to be turned around and towed out to sea. As two tugs attempted to pull the *Urquiola* clear of the harbor, it grounded again, this time tearing a large gash in the bow storage tanks. Oil poured into the water, and *Urquiola* listed  $10^{\circ}$ . The smell of petroleum near the ship was almost overpowering.

The crew was ordered off the ship, but the captain stayed onboard to help coordinate salvage and lightering efforts. Two hours later, *Urquiola* exploded in a ball of flame and black smoke that set the sea on fire within several hundred yards of the ship. The captain was killed, and for the next 16 hours the burning oil, combined with an onshore breeze, spread a cloud of choking volatile gases over La Coruña and all areas within 62 miles (100 km) of the wreck. During the morning of May 14, a second explosion and fire blasted through *Urquiola*, and oil began to leak from the stricken vessel at the rate of 2,200 barrels (433 metric tons) per day. The *Urquiola* was not safe to approach for a week, but lightering began on May 21, and 50,000 barrels (9,844 metric tons) of crude oil was removed before bad weather halted off-loading on May 25. *Urquiola*'s stern section eventually broke apart in the heavy

seas with 10 to 15-foot (3–4.6-m) waves. The stern contained most of the sailing fuel, 22,000 barrels (3.5 million L) of Bunker C, and it was towed to a more protected area in the western part of the harbor for lightering. Unfortunately, a crack developed in one of the fuel storage tanks, and some oil was discharged into this previously unaffected area of the coastline. Overall, 100,000 tons (90,719 metric tons) of oil was discharged into the environment as a result of the *Urquiola*'s grounding.

### ENVIRONMENTAL AND ECONOMIC IMPACT

The response of the Spanish government included the immediate application of more than 2,000 tons (1,814 metric tons) of dispersant chemicals from 11 ships, both directly on the oil slick and along shorelines. Heavy seas and the lack of an official and documented spill response contingency plan limited the effectiveness of booms, skimmers, and other waterborne mechanical collection devices. By June 3, approximately 25,000 tons (22,680 metric tons) of oil had contaminated more than 130 miles (215 km) of coastline, 40 miles (64 km) of it described as "heavily" oiled. Onshore, a small contingent of about 100 workers using buckets and shovels, as well as 15 pieces of heavy equipment, attempted to remove the oil and froth from accessible shoreline areas.

This part of the Galician coast is characterized by submerged V-shaped valleys that form large embayments, locally called *rias*. The *rias* are protected from the full force of the Atlantic Ocean by steep, rocky headlands and a marsh-tidal flat system or by a small (less than 0.6 mile [1 km]) rocky or sandy coastline that can occur inside of them. As *Urquiola*'s oil was driven landward, its distribution within the three most impacted *rias* (Rias de la Coruña, Rias Area, and Rias Betanzos) was influenced by wave action, tidal stage, and the composition of beach material. Spring tides, those unusually high and low ocean levels that take place during the full moon, carried much of the oil ashore and distributed it across a wider area of beach face than it normally would have covered. This oil, which was deposited above the area of typical wave action, tended to be more persistent and difficult to clean up.

Oil making landfall in areas of intense wave action was buried deeper and more rapidly than those portions of the slick blown or carried into lower-wave-energy *rias*. On beaches made up of fine-grained sand, the oil coating the sediment was primarily superficial and penetrated less than 0.8 inch (2 cm) below the surface. This was because of the lower permeability and higher density of these

finer-grained and more compacted sediments, which greatly reduced the ability of the oil to migrate into the subsurface. In areas where the coastline was rocky, wave energy and lack of porous materials contributed to a faster natural cleaning and restoration, although initial effects on lichen and algae living on or attached to the rocks were often devastating. On coarse sand or mixed (coarse and fine sand) beaches, the oil penetrated deepest and was most difficult to remove. Wave action on these types of beaches tends to be more aggressive and sediments more porous and permeable, allowing oil to penetrate to depths of 12–24 inches (30–60 cm). The early, indiscriminant use of dispersants on shore may have contributed to the oil's ability to move deep below the surface in these areas.

Ecologically, more than 70 percent of the edible cockle, an important shellfish in this part of La Coruña, was killed off by either oil or dispersant. Populations of other shellfish species declined 10–30 percent and, because of their slow growth rates, required several years to recover to predisaster levels. Near-shore fishing for sardine and hake was banned, although deep sea fishing away from the wreck continued. The bird mortality rate was fairly low, with the majority of deaths in native gull species. Economic losses were estimated at approximately \$3 million and spill cleanup costs in the \$95-million range. The *Urquiola* was a Spanish-flagged ship on charter to the national oil company, and, as such, the Spanish government assumed responsibility for the spill and its aftermath.

**Usinsk oil spill Usinsk, Russia (October 1994) Soil Pollution** In 1982, the United Nations Convention on the Law of the Sea, an international agreement that resulted from the third United Nations Conference on the Law of the Sea, extended countries the exclusive rights to all natural resources on and underneath their continental shelves, up to 200 miles (322 km) from shore. The enormous submerged continental shelf off the northern, Arctic coastline of Russia became available as a result of this agreement. Along this northern continental shelf, which reaches into the Barents Sea and Arctic Ocean, under the frigid water and thousands of feet of silt and sand are some of the largest untapped deposits of oil and natural gas in the world. Estimates of the amount of potential hydrocarbons present in rocks that were deposited when Russia had a tropical climate indicate 90–100 billion tons (82–91 billion metric tons), with natural gas accounting for 80 percent of the volume. Oil- and gas-bearing areas may be present in more than 90 percent of the Russian continental shelves, about 2.3 million square miles (6 million km<sup>2</sup>). Discovered with only limited exploration, two very large oil and gas basins in the West Arctic on the shelves of the Barents and Kara Seas cover 0.8 million square miles (2 million km<sup>2</sup>) and contain potential resources of at least 50–60 billion tons (45.4–54.4 billion metric tons) of oil and natural gas.

This very large potential reserve of hydrocarbon, although present in remote and climatically extreme areas, represents not only energy security for Russia, but also a source of currency that, if managed properly, can be used to stabilize the economy and raise the standard of living for all of its citizens. The Russian government is eager to develop this important natural resource and the small city of Usinsk, just south of the Arctic Circle and 1,000 miles (1,609 km) from Moscow, is at the center of that effort. Winters there are long and cold, with only a 20-week-long mild spring/summer. This settlement of a few thousand oil field workers could become a major petroleum center. The Russian government

will have to decide to build a new, modern transcontinental pipeline to transport the oil and natural gas to Europe or to a yet-to-be-built terminal only a few miles to the north on the Arctic Ocean.

At present, however, the oil at Usinsk is pumped from the Kharyaga oil field of the Timan-Pechora Basin into a creaky 1972-vintage 29-inch- (73.7-cm-) diameter, 11.2-mile- (18-km-) long pipeline that connects with other pipelines. The oil is then sent to refineries operating in the more moderate climates of interior Russia. There are no facilities to capture and ship the methane recovered with this oil, and it is flared or burned. These giant flares, visible on satellite photographs from outer space, consume the same amount of natural gas that is used annually in Denver, Colorado.

### THE OIL SPILL

In October 1994, Usinsk became the site of one of the largest land-based oil spills on record, and it had devastating consequences for its local ecology. Four separate sections of the Usinsk pipeline had been leaking since February of that year, and the Russian oil company responsible for its repair and maintenance, KomiNeft, or Komi Oil, opted to capture the oil from these leaks and pump it to an area enclosed by an earthen berm or dam, rather than lose the revenue and incur the costs associated with stopping the flow of oil to make necessary repairs. This berm created a large oil lake or moat, holding more than 1.5 million barrels, or almost 60 million gallons (227 million L). Leakage from the KomiNeft pipeline has been linked to the practice of adding river water to the oil to help it flow. This water, however, tends to accelerate corrosion of the bare metal pipeline, especially near fittings and connections.

**Burning oil from the Usinsk pipeline spill, Siberia, December 1994 (Mark Warford)**

As the Russian winter began in earnest, the hastily constructed berm started to deteriorate from the alternating rain and snow with below-freezing temperatures. On October 1, a section of the berm collapsed and a torrent of oil was released into the ecologically fragile Siberian landscape. The oil flowed overland, making its way into local streams and drainage channels, and eventually covered more than 0.3 square mile (70 ha). Once released into the arctic climate of northern Russia, the oil was resistant to both evaporation and biological breakdown because of the low temperatures. In addition, the frozen ground slowed infiltration, and oil readily moved great distances over the landscape.

The Usinsk oil flooded into the Kova and Usa Rivers, which serve as important tributaries to the Pechora River, a major salmon fishery and habitat for many land-based species of plants and animals. The Pechora River flows into the Pechorskoye Sea, which gradually transitions into the Barents Sea.

### THE CLEANUP

At the time of the spill, KomiNeft was reportedly pumping about 4,000 tons (3,269 metric tons) of oil per day through the pipeline. This continued for several weeks after the spill began, until local officials were able to convince the company to shut down the pipeline temporarily to complete cleanup operations more effectively. Fortunately, the cold weather helped in oil containment and recovery, with cleanup consisting of bulldozers and other types of earth moving equipment used to scrape the layer of contaminated soil off the ground. This method, however, had the unfortunate side effect of destroying vegetation and other types of ground cover that had taken many years to become established in the short growing season of the inhospitable climate. As examples, trees take decades to grow a few feet and tire tracks in tundra grass remain visible for up to a half-century in this area. Workers simply set the oil afire if it was inaccessible in narrow stream channels, for example, or too difficult to remove. This practice further destroyed the fragile habitat. KomiNeft, the company responsible for the operation of the pipeline and cleanup of the spill, explained these tactics as necessary to prevent a more extensive disaster in the springtime, when warmer temperatures would make the oil more mobile.

This was not the first time oil was released from this pipeline. KomiNeft regularly tried to repair leaks and recover oil spilled from hundreds of discharges along the 11.2-mile (18-km) length of exposed and unprotected pipeline. Similar spills occurred in 1988, when more than 20,000 tons (18,144 metric

tons) of oil was released, and in 1992, when two pipeline breaks each released an estimated 30,000 tons (27,216 metric tons) of oil. International oil production experts estimated that Russia may lose as much as 20 percent of its produced oil from both pipeline leakage and theft of oil. The amount of oil released by the Usinsk spill is only exceeded by that intentionally discharged by the retreating Iraqi army in Kuwait at the end of first Persian Gulf War.

### FAR-REACHING EFFECTS

The 1994 spill and the spills that have occurred since then place at risk one of the largest herds of domestic and wild reindeer in Russia, estimated at 120,000 animals. For fodder, reindeer depend heavily on lichen, which grows as part of the ground cover throughout this region. If the lichen are damaged or destroyed by oil, the reindeer herds starve. The Barents Sea just north of Usinsk is a favorable habitat for one of the largest concentrations of white whales or beluga (of *Moby-Dick* fame) in the world. The beluga whale is known to swim upriver to feed on freshwater fish. This places it at an increased risk for damage from inland oil spills. Portions of the coastlines along the Pechorskoye and Barents Seas, which are major commercial fisheries, stay free of ice until mid-December and are essential breeding grounds for numerous types of seabirds and fish species.

The area where the spill took place is remote and not very populated. The initial release flooded approximately 0.3 square mile (70 ha) of tundra. Spring rains and floodwater pushed the oil across another eight square miles (2,100 ha), much of which was used as grazing land for reindeer herds. Some settlements and herders reported up to 90 percent of grazing and fodder-producing land was contaminated. The economic impact was estimated at \$103 million, and, with the cost of the lost oil and future cleanup added to the estimate, damages are almost \$500 billion. The U.S. Environmental Protection Agency (EPA) and Canadian environmentalists estimated that up to 220,462 tons (200,000 metric tons) of oil had been discharged; however, official Russian estimates are closer to 16,535 tons (15,000 metric tons).

### THE AFTERMATH

The Russian government fined KomiNeft the equivalent of \$600,000 for the 1994 spill and ordered them to begin cleanup operations immediately. The company was unable to pay most of the fine, however, because of a lack of financial resources. Instead, they gave local residents up to seven dollars each as

compensation for the ecological and environmental damage caused by the spill. Under pressure from the world community, Russia eventually agreed to allow foreign oil cleanup experts, a joint U.S.-Australian company, to assist KomiNeft in addressing the impacts of the spill. The European Bank for Reconstruction and Development loaned \$25 million for the cleanup operation, and the World Bank provided another \$100 million. Since the 1994 release, the oil containment berms around the leaking pipeline have been either rebuilt or reinforced, and work on improving pipeline integrity is ongoing.

In 1999, KomiNeft and its parent company, Komitek Oil Company, were purchased by LUKoil. Founded in western Siberia, LUKoil has developed into one of the major providers of oil and gas in Russia. The dissolution of KomiNeft represents only a part of the solution for the aging and inefficient Russian oil industry. Russia has only recently begun to allow the limited participation of outside oil companies in exploration and development projects as well as permitting them to improve and expand downstream refining and distribution systems. LUKoil has a reputation for aggressively pursuing joint venture opportunities with companies such as BP and Shell, and with these expanded business operations it is hoped that there will be a more sophisticated understanding and dedication to environmental protection.

**Valley of the Drums Brooks, Kentucky (1967–2016)** *Water Pollution* Often cited as one of the reasons for the awakening of Al Gore's environmental consciousness, the A. L. Taylor site just outside Brooks, Kentucky, and only 125 miles (201.2 km) from the Tennessee border, played a key role in the passage of the Comprehensive Environmental Responsibility Compensation Liability Act, or CERCLA. The A. L. Taylor site was better known as the Valley of the Drums, and the startling and disturbing pictures from this site, combined with the disasters at Love Canal, New York, and Chemical Control Corporation, New Jersey, served to galvanize Congress and the nation into enacting some of the toughest waste control and environmental management programs in the world. It was in this way that, in 1975, the small town of Brooks, Kentucky, found itself at the center of the American environmental movement in its quest to address the cleanup of abandoned industrial waste sites.

## **POLLUTION OF THE SITE**

In 1966 and 1967, A. L. Taylor, a local landowner, decided to start a small drum recycling operation on his property. The property was typical of the north-central part of Bullitt County, with high walls with steep slopes on one side of a valley and lower, gentler slopes on the other. Mr. Taylor began by visiting local paint and coating industrial operations in nearby Louisville, Kentucky, and convinced them to send him their empty and partly full drums of solvents, paints, and chemicals. Taylor recycled these drums by emptying their contents into one of the five large pits he had dug on his 13-acre (5.3-ha) property, washing the drums out, with the rinsate

also going into the pit, and then either returning the drums to the customer or selling them as reconditioned containers. When the pits were full, Taylor simply set them on fire to burn off the residuals. Providing a much-needed service to his customers, A. L. Taylor was able to offer a very competitive price because he had not bothered to obtain the necessary permits to operate a waste disposal facility from the state of Kentucky.

The A. L. Taylor Drum Cleaning Service first attracted the attention of the Kentucky Department of Natural Resources and Environmental Protection Cabinet (KDNREPC) in 1967 after they received a report of a fire that had been burning for a week in one of the on-site waste pits. Despite being ordered to cease operations, Mr. Taylor continued to accept wastes and drums for on-site disposal and reprocessing, in direct defiance of aggressive legal action by KDNREPC. He agreed to stop burning wastes and eventually used soil from a nearby hillside to fill in and cover the pits. A. L. Taylor died in 1977. At that time, literally thousands of drums remained stored on the property, many of them full of liquid wastes and in poor condition.

Soil samples collected from around and within the waste pits and drum storage areas contained high concentrations of heavy metals, ketones, phthalates, polychlorinated biphenyls (PCBs), chlorinated alkanes and alkenes, aromatics, and polycyclic aromatic hydrocarbons (PAHs). Approximately 140 hazardous compounds were found to have been released to the environment at the site.

The main threat to public health and the environment was the physical presence of the waste materials in the Valley of the Drums, rather than its release into surface water or groundwater systems. Surface

runoff from the property entered a drainage ditch that flowed into Wilson Creek, a tributary of Pond Creek, which, in turn, empties into Salt River. The Salt River discharges into the Ohio River. The long pathway of more than 20 miles (32.2 km) for contaminants in the surface water to travel from the A. L. Taylor site to the Ohio River resulted in a dilution factor of greater than 1,000,000 to 1 before any drinking water intakes on the Ohio River were encountered.

The A. L. Taylor site is in the Knobs physiographic region of Kentucky, an area dominated by Middle to Late Paleozoic sedimentary rocks. Groundwater at the site occurs in two aquifers, a shallow unconfined soil aquifer and a deeper confined rock aquifer. Water table levels range from 2.4 feet (0.7 m) to 6.4 feet (2 m) below the surface. Shallow groundwater flows toward Wilson Creek. The topmost layer of rock in the area is impermeable shale, which tends to impede groundwater movement. The deep aquifer occurs in limestone under the confining shale and yields most of the water pumped from consolidated rocks in this area of the state. Water is contained in and moves along interconnected fractures and solution channels. Little local use is made of the shallow or deep aquifers, and no wells penetrate the deep aquifer near the A. L. Taylor site. Although fairly rural, the Valley of the Drums was bordered by a golf course and about a half-dozen private residences. These properties received their drinking water from cisterns or were connected to the Louisville municipal water supply system.

### NATIONAL ATTENTION ON THE PROBLEM

By 1979, KDNREPC realized they did not have the financial or technical resources needed to address the more than 17,000 partially full or empty drums present on the A. L. Taylor property. With no funding or administrative mechanisms yet available to address environmental effects of abandoned industrial wastes, the U.S. Environmental Protection Agency (EPA), founded only a few years earlier, in 1970, cleverly used their authority under Section 311 of the recently enacted Clean Water Act to allow federal funds to be used to construct interceptor trenches and a temporary granular activated carbon (GAC) water treatment system to prevent contaminated runoff from entering Wilson Creek.

During this time, the national media focused the country's attention on sites such as Valley of the Drums, and, on December 11, 1980, Congress passed and President Jimmy Carter signed CERCLA into law. One of the most important parts of this groundbreaking legislation was the development of the National Priorities List (NPL). This list served as

a compendium of the worst abandoned or inactive hazardous waste disposal sites in the United States. These sites were regarded as imminent dangers to public health or the environment. To provide money to clean up these sites, a tax was imposed on the petroleum and chemical industries, with those revenues going to a "Superfund," a large pool of dollars created to fund the cleanup of those types of facilities. Valley of the Drums was near the top of the first NPL list published by the EPA.

Another key component of CERCLA was the establishment of joint and several liability for those who caused or contributed to the contamination. Any business, company, or person whose activities resulted in the illegal disposal or release of hazardous substances or materials was responsible for the cleanup of the entire spill or release, not just the part of it that was his fault. Using this new legislative authority, KDNREPC contacted five responsible parties (RPs) identified as having sent drums to the A. L. Taylor site for "recycling": Ford Motor Co., Reliance Universal Inc., Louisville Varnish Co., George W. Whitesides Co., and Kurfee's Coating, Inc. These companies paid for the removal and disposal of the remaining drums on the site and subsequently reimbursed the USEPA and KDNREPC for much of the soil cleanup and site stabilization activities.

Once the immediate danger had been addressed, the EPA and KDNREPC began extensive negotiations with the RPs for a long-term remedy at the site. On the basis of technical, community, and cost factors, the remedy selected consisted of removal and off-site disposal of leachate or water present in the waste pits; stabilization of pond sediments, sludge, and other debris from low-lying areas; and installation of a cap across the waste now buried in the pits and elsewhere on the site.

The cap was the centerpiece of the remedial solution; it was made of a 30-inch- (76.2-cm-) thick layer of impermeable clay, overlain by an 18-inch- (45.7-cm-) thick layer of another impermeable material. A six-inch- (15.2 cm-) thick layer of topsoil was placed as final cover and planted with cover plants that had root systems that stabilized the topsoil and loam against erosion but will not penetrate the clay material of the cap. This cap is designed to prevent waste materials, or leachate, from being washed off the site by surface water.

A surface water drainage diversion ditch, which routes runoff around the capped area and can accommodate a 25-year 24-hour storm intensity, also was constructed. A monitoring program was implemented for Wilson Creek, to make sure contaminants were not leaving the site via a surface water flow pathway; groundwater monitoring down-

gradient of waste disposal areas also was part of site closure requirements. Finally, the site was secured with a six-foot- (1.8-m-) high chain-link fence and will be inspected regularly until 2016.

As directed by Congress, every five years, the EPA must evaluate the effectiveness of the remedies it has selected for each Superfund site. Four five-year reviews were conducted at the Valley of the Drums in 1992, 1997, and 2002, and 2007. In each case, the reviews concluded that the remedy implemented at the A. L. Taylor property remains protective of human health and the environment. The site was deleted from the National Priorities List in June 1996 and now serves only as a reminder of an era when the uncontrolled disposal of hazardous and toxic wastes constituted a major threat to the health and safety of the United States and its citizens.

**Vermiculite Mountain Libby, Montana (2000–2007) Air Pollution** Vermiculite is a broad term applied to a set of minerals formed when groundwater has contact with and geochemically alters micas. Micas are aluminum silicate minerals that are common in igneous and metamorphic rocks. They have a distinctive cleavage, tending to split into

thin, flexible sheets, or plates. Vermiculite forms when water is incorporated into the laminar structure of magnesium-aluminum-iron silicate micas. Essentially, vermiculite is mica weathered by water introduced or added into the platelike structure of the mica sheets. Vermiculite forms most readily when two types of mica, biotite and phlogopite, are altered in this way.

An important industrial mineral, vermiculite has been used for almost a century as an insulator, sound deadener, soil conditioner, absorbent in packaging, and, most significantly, a fireproofing agent. Vermiculite is able to serve this wide range of uses because of its ability to exfoliate and expand (pop or puff) if heated at relatively low temperatures (1,472–2,012°F [800–1,100°C]) for only a few seconds. This expansion results when the water trapped between mineral layers is rapidly converted to steam. The expansion produces a 10-fold reduction in the bulk density of the mineral, from a dense 40–70 lb./ft.<sup>3</sup> (640–1,120 kg/m<sup>3</sup>) to a very light 4–10 lb./ft.<sup>3</sup> (64–160 kg/m<sup>3</sup>).

After it "pops," the processed vermiculite is lightweight, burns only at a high temperature, and readily traps air and water, making it suitable as an insulating agent and soil conditioner. It also changes size and shape, increasing to around eight to 12 times its original volume and forming small tubelike open-ended cylinders. This chemically inert, fire-resistant, and odorless material provides good thermal insulation and can absorb liquids such as fertilizers, herbicides, and insecticides, allowing them to be shipped as loose, free-flowing solids.

Today, most of the world's vermiculite is obtained from mines in South Africa, China, Brazil, and Zimbabwe. It also is mined in the United States, from deposits along the eastern Appalachian Mountains in Virginia and South Carolina. In the early 1920s, the United States was poised to become the world's largest producer of vermiculite, with the major source of this material a newly opened mine in the small town of Libby, Montana.

#### BACKGROUND

The Libby vermiculite deposit was discovered in 1919 when a local hotel owner decided to try his luck at gold prospecting. He visited some old workings at a nearby mountain, and, although he did not find any gold, he did notice that the rocks that had contact with his open-flame carbide lantern sputtered and popped when he stood too close to them. Curious, he sent a sample of the material to the U.S. Bureau of Mines, which subsequently informed him that the material was vermiculite and quite valuable. This man eventually sold his hotel, mortgaged his

ranch, and, by 1924, had become a full-time miner, building a small plant to size and exfoliate (pop) the vermiculite after it had been removed from the open pit he was digging. By 1925, the material was being shipped around the country, used to insulate bank vaults and added to roofing asphalt to improve its durability and fireproofing. In 1926, more than 100 tons (90.7 metric tons) of vermiculite per day was produced from the Libby workings.

The geology of the Libby vermiculite plays an important role in the environmental and public health effects related to its exploitation and widespread use. The Libby mine is about seven miles (11.3 km) northeast of the town, just above the banks of Rainy Creek. The bedrock in this part of northwestern Montana is made up of very old (about 600 million years) metamorphosed sedimentary rocks. Later (250 million years ago), an alkaline-ultramafic magma forced its way into this bedrock. This igneous intrusion is known as the Rainy Creek Complex, and, as the molten mass cooled, minerals such as biotite were formed. This and other minerals crystallized in the molten magma in a predictable pattern and formed concentric zones within the solidified rock mass.

The vermiculite at Libby was not formed until after the Rainy Creek Complex had been injected and

allowed to cool. As hot saline fluids from the solidifying rock mass and surrounding country rock as well as from later igneous intrusions encountered the biotite of the Rainy Creek Complex, the black micas began to change. Hydrothermal alteration is a chemical reaction in minerals brought about by hot fluids moving through the rocks. It was this hydrothermal alteration, combined with subsequent near-surface weathering processes, that carried the water into the crystallographic structure of the biotite and created vermiculite. The hydrothermal solutions also reacted with the mineral pyroxene, which is widespread throughout the Rainy Creek Complex, and intimately associated with the biotite, to form the mineral amphibole.

It was this geochemical reaction (the creation of amphibole) that would later result in the deaths of at least 200 people, the bankruptcy of a Fortune 100 company, and one of the nation's most extensive Superfund cleanups.

### CONTAMINATION OF THE AREA

An important group of more than 60 different rock-forming minerals, amphiboles are present in most igneous and metamorphic rocks, and almost all are harmless. They form at lower temperatures and

**Les Skramstad (right) developed asbestosis from working in the W. R. Grace vermiculite mine in Libby, Montana. He opposes mining industry efforts to limit lawsuits in asbestos cases. Seattle, 2003. (AP Images)**

always in the presence of water. Five major amphibole minerals—amosite, also known as grunerite or cummingtonite; crocidolite, tremolite, actinolite, and anthophyllite—can form asbestiform minerals. A sixth type of asbestiform mineral, chrysotile, is not an amphibole but belongs to a class of minerals called serpentines.

*Asbestiform* is a morphological term used to describe the appearance or habit of a mineral that has crystallized or grown in a single dimension. These types of crystals form long fibrous threads with length-to-width ratios of 20:1–100:1 or greater. When stressed, asbestiform minerals do not shatter; rather, the fibrous crystals bend and are pulled apart, sometimes breaking into shorter strands. Nonasbestiform varieties of tremolite, actinolite, and anthophyllite also occur naturally.

Asbestiform minerals have great economic significance. They are resistant to acids and strong bases, are effective electrical and thermal insulators, and the highly flexible and mechanically durable fibers can be easily woven or incorporated into cloth or other materials such as cement or asphalt. This group of minerals generally has been lumped together and defined as or called asbestos and has been used in brake linings, fireproofing compounds, and hundreds of types of building, flooring, and roofing materials. Despite all these useful properties, by the late 1970s asbestos began to be phased out of general use in the United States. The reason is that when inhaled, asbestos fibers can result in damage to the respiratory system and may even cause cancer. Recent studies have indicated that the amphibole forms of asbestos are more hazardous than the chrysotile type. This is because, when broken, the amphibole asbestos fibers are brittle and needle sharp. The chrysotile asbestos fibers are more flexible and arcuate and tend to do less damage when inhaled and lodged in the lungs.

The vermiculite at Libby is closely associated with asbestiform amphiboles, particularly tremolite, although winchite and richite, two other, less common varieties of amphibole asbestiform minerals, also are present in significant amounts. When the vermiculite ore at Libby was extracted and processed, asbestos-laden dust was released. Also, asbestos remained in the final product and was released during shipment and placement of the material.

Mining at the Vermiculite Mountain deposit was not a technologically challenging procedure. The ore body was within a few feet of the surface, covered only with a thin layer of soil. Once this was stripped off, the ore was dug out with standard excavating equipment, loaded onto large trucks, and driven to the mill for processing. Later, an open conveyor

was installed to transport the raw ore from the mine workings and deposit it in huge piles at the mill near town. The ore was then graded or sized and heated with steam until it popped. The finished product, named Zonolite, was then bagged or loaded into railcars for shipment. In some cases, unprocessed ore was sent to distant processing mills, some as far away as New Jersey, for exfoliation (popping).

In 1939, the original operations merged with another mining company, which began extracting ore in a different area of the deposit, and the Zonolite Corporation was formed. In 1963, W. R. Grace purchased Zonolite Corp and quickly expanded mine and processing activities, and soon the Libby workings became the world's largest producer of vermiculite, supplying more than 80 percent of this material. Mr. William R. Grace founded the company that bears his name in 1854 in Peru, where he bought and shipped bat guano for use as fertilizer. Over the years, Grace has changed from primarily a shipping and transportation organization into one of the world's largest specialty chemicals and materials companies with more than 6,000 employees and \$2.5 billion in annual sales.

Between 1963 and 1990, Grace and its on-site management team operated the mine efficiently and cost-effectively, realizing more than \$180 million in after-tax profits from the sales of Zonolite and Zonolite-based products. These operations were flawed in one very serious way: Every step of Zonolite mining, from extraction through exfoliation and shipping, produced dust. Asbestiform minerals were in that dust.

Through the 1970s and 1980s, as the dangers of both occupational and nonoccupational exposure to asbestos fibers became well known, the U.S. Environmental Protection Agency (EPA) began to take an interest in the workings at Libby, especially when, in 1978, workers at a chemical fertilizer plant in Marysville, Ohio, began to exhibit symptoms of asbestos-related diseases. This plant had used vermiculite ore in its fertilizers, and Libby vermiculite was thought to be the source of asbestos that had damaged the workers' health. On the basis of this information, the EPA began to focus on the potential risk of asbestos-contaminated vermiculite. In 1982, it sampled vermiculite at three major U.S. mines, including Libby. Other factors, however, intervened to shift EPA scrutiny away from Libby and vermiculite.

### INACTION OF REGULATORY AGENCIES

First, laboratory findings of the vermiculite samples reported that asbestos fibers in the samples were less than 1 percent, not considered significant at that

time. Next, EPA was beginning to feel national pressure to do something about asbestos in schools. The agency regarded asbestos-contaminated vermiculite as a less significant risk than asbestos-containing materials in schools and commercial or public buildings. As a result, EPA redirected its enforcement resources to these other asbestos materials and products. Grace quietly ceased operations at the Libby mine in 1990 because the price of vermiculite was falling as a result of recent discoveries in Africa and Asia, and the Montana operations were no longer profitable.

In 1992, a citizen wrote a letter to EPA complaining about potential exposure to asbestos when a building at the inactive vermiculite-processing mill was torn down. EPA referred the complaint to the Montana Department of Environmental Quality (DEQ), which investigated and found that the demolition had taken place without removing the asbestos from the building or taking the appropriate steps to prevent its airborne release, which are required under the Clean Air Act. The mine owner, Grace, was fined more than \$500,000.

Another citizen complaint, in 1994, identified blowing dust from the inactive mill site and an adjacent unused haul road as having an adverse impact on the health of Libby's residents. Once again, the Montana DEQ investigated, collecting soil samples from the mill site and haul road. Although asbestos was found in the samples, the DEQ did not take any action because the asbestos detected in the vermiculite at the mill site and on the road was not considered to be commercial asbestos. Commercial asbestos is asbestos that is produced from the mining of asbestos ore. Vermiculite was not mined for its asbestos content and, therefore, was exempt from regulation under the Clean Air Act. In 1995, the EPA advised the citizen that neither the DEQ nor EPA planned any action based on the DEQ's findings.

Nothing happened for more than five years at Libby, except that many of its citizens grew sicker. In 1999, a groundbreaking series of investigative reports published in the Seattle newspaper the *Post Intelligencer* titled "Uncivil Action—a Town Left to Die" pushed the problems of Libby into the forefront of national attention. The story told of the deaths and illnesses of more than 500 current or former Libby residents exposed to the asbestos-contaminated vermiculite ore and asserted that asbestos from the Libby mine and mill was still present in schools, homes, backyards, and buildings throughout the town, continuing to be a major threat to public health.

In the face of such damning publicity, both the EPA and DEQ were forced to act. Shortly after the newspaper articles were published, the EPA sent an investigation team to Libby, where, along with an official from the Montana Department of Health, they interviewed residents, examined health records, and collected more than 2,000 soil, dust, and building material samples for asbestos analysis. They discovered that more than 30 percent of the samples contained asbestiform tremolite. The EPA and DEQ studies also identified several residents who had contracted nonoccupational asbestos-related diseases. Later investigations confirmed that between 1979 and 1998, the death rate in Libby of asbestosis was 40–80 times higher than that in other areas with similar demographic makeup, and, in 2001, X-rays of more than 6,700 Libby residents and former mine workers found that 18 percent had asbestos-related lung damage.

### THE CLEANUP

These and other findings finally compelled the EPA to begin cleanup activities at Libby in 2000. Their efforts ranged from digging up and replacing asbestos-contaminated soil in schoolyards and playgrounds to using special high-efficiency vacuum cleaners to remove asbestos-laden dust from people's homes. Remedial efforts at Libby continued through the end of 2007 and cost more than \$180 million. This does not include an additional \$7 million to address contamination at more than 170 sites in other parts of the country that received the asbestos-contaminated ore from Libby. The work was performed under the Superfund program, which authorizes EPA to force responsible parties to do the work. If the responsible party, in this case, Grace Company, is unwilling or unable to comply with a cleanup order, EPA can move forward with site remediation and recover its costs from those who caused the contamination.

In June 2009, EPA for the first time in history used its authority under CERCLA to declare a public health emergency in Libby. While no one will be evacuated, this declaration does help provide priority funding for cleanup activities. As a result of previous and ongoing cleanup actions by EPA and its contractors, the former vermiculite processing plants and other highly contaminated public areas have been remediated. Cleanups also have been finished at 1,100 residential and commercial properties. EPA completed asbestos stabilization and removal actions at 100 larger properties by the end of the 2010 construction season. The EPA estimated that 1,200–

1,400 remaining residential and business properties needed some type of cleanup.

### LEGAL ACTIONS AGAINST GRACE CORPORATION

Grace's response to the Libby contamination was carefully crafted to protect their business interests and to help ensure the survival of the company. EPA was forced to sue Grace for the Libby cleanup because Grace refused to pay, stating that the EPA was doing much more than just emergency remediation; it was "rehabilitating" the property, and rehabilitations costs were not recoverable under Superfund. The federal courts disagreed and ordered Grace to reimburse EPA more than \$50 million for the first phase of its work. As the number of asbestos-related lawsuits against Grace began to rise, filed by both workers and people who became sick as a result of using Zonolite and related products in their homes and businesses, the company filed for bankruptcy protection in 2001. Before this, however, it had transferred millions of dollars in assets to foreign subsidiaries. A bankruptcy court judge later ordered Grace to return those assets to control of its U.S.-based operations.

In 2005, the EPA and U.S. Attorney's Office filed criminal indictments against Grace and seven of its executives, including two former mine managers, of knowingly releasing asbestos into the air, thereby endangering miners, their families, and townspeople, and of obstructing the investigation efforts of the EPA. Part of the indictment accuses executives and managers of the mining company of allegedly concealing health risks at the mine. For example, one company memorandum, written in 1976 by one of the indicted executives, states that almost two-thirds of employees who had more than 10 years of service tested positive for lung damage. If convicted, the managers and executives faced up to 15 years in prison. As a company, Grace could be fined up to twice the profits it made from the Libby mine, estimated at \$140 million, or be ordered to pay restitution to the victims. The trial began in late 2006, after a failed attempt to change the venue from Missoula to San Francisco. Grace consistently and vehemently denied any wrongdoing, and, in May 2009, Grace (the corporate entity) and three former executives were acquitted by a Montana jury of charges of knowingly exposing workers and townspeople to asbestos and subsequently conspiring to cover up those exposures. Grace funds an extensive medical monitoring and prescription drug plan for the residents of Libby and donates regularly to the local hospital.

The former Libby mine has been sold to three local townspeople, who have not yet decided how to develop it. Up to 100 years worth of mineable vermiculite ore is estimated to remain below the mountain.

**vinyl chloride** In most cases, when a chemical is found to pose an environmental and/or health threat, its usage declines. Vinyl chloride, however, is one of the highest-volume chemicals used in the United States with ever-increasing demand, and yet it is one of the most deadly. This high volume leads to a widespread distribution, which is demonstrated by its presence in at least 616 of the 1,662 current or former U.S. Environmental Protection Agency (EPA)–designated Superfund sites (on the National Priorities List). The widespread nature and threat to health and the environment led vinyl chloride to be named the fourth worst pollutant in the United States on the 2007 CERCLA Priority List of Hazardous Substances. As a result, its use was strongly limited in 1974 through the passage of the Safe Drinking Water Act by the U.S. Congress because of its adverse health effects. The problem is that vinyl chloride, which is also known as chlorethene, chlorethylene, monochlorethene, monovinyl chloride (MVC), and Troidur, is used by the plastics industry to produce the extremely popular polyvinyl chloride (PVC), for which there is no other source. Until some other method to produce PVC is found or a substitute for PVC is found, it is likely that

vinyl chloride will continue to be produced in ever-increasing quantities.

### PROPERTIES, USES, AND PRODUCTION

Vinyl chloride is a synthesized organic compound that does not occur naturally but can be formed in the natural environment through the natural breakdown of other synthesized organic compounds. It is a chlorinated aliphatic hydrocarbon that at standard conditions is a sweet-smelling gas that is extremely flammable and even explosive. If mixed with air, it produces a deadly and irritating gas rich in carbon monoxide, hydrogen chloride, and phosgene. It only forms a liquid under high-pressure or low-temperature conditions.

Vinyl chloride was invented in 1835, but an efficient method of producing it was not discovered until 1912. As a result, the first commercial production of vinyl chloride did not begin until the 1920s. Prior to 1974, vinyl chloride also had uses as a refrigerant, extraction solvent, aerosol propellant, ingredient in pharmaceuticals and cosmetics, and even as an anesthetic in medical procedures. Now, more than 95 percent of vinyl chloride is used in the production of PVC and its copolymers, which have an enormous variety of applications such as furniture, electric wire insulation and cabling, building and construction supplies, pipes and plumbing supplies, automotive parts and accessories, medical supplies, packaging of all types, industrial and household equipment, sporting and outdoor equipment, military equipment and supplies, resins and film, and numerous other applications from credit cards to compact disks (CDs) and digital video disks (DVDs). As a result of these vast applications, vinyl chloride ranked as the 17th highest-volume chemical produced in the United States in 1994 and the 18th in 1995. Production increased from the late 1970s at 6–9 billion pounds (2.7–4.1 billion kg) per year to the mid-1990s at 15 billion pounds (6.8 billion kg) per year, a growth rate of about 7 percent per year. By 2003, there were 13 producers and 10 suppliers of vinyl chloride in the United States, and the production growth rate continues at about 3 percent per year. Imports of vinyl chloride peaked in 1989 at 302 million pounds (137 million kg) per year and had generally declined to 168 million pounds (76.2 million kg) per year in 2002, while exports fluctuated from 685 million pounds (311 million kg) per year to a high of 2.3 billion pounds (1.03 billion kg) per year in 2000.

### ENVIRONMENTAL RELEASES

Vinyl chloride enters the natural environment almost exclusively through waste and emissions from the plas-

tics industry, which uses it, and the chemical industry, which produces it. High environmental exposure to it only occurs near these industrial sites or in hazardous waste sites and landfills where leakage has occurred. Outdoor air in both rural and urban areas in the United States generally contains lower levels of vinyl chloride than the detection limit of the equipment. It is also not generally found in drinking water, again below the detection limit of the testing equipment for all but 0.74–0.9 percent of the population. Industrial releases of vinyl chloride to the environment slowly declined from an annual rate of 1.4 million pounds (635,000 kg) in 1988 to less than 1 million pounds (454,000 kg) by 1990. In 2001, 49 manufacturing and processing facilities released 732,200 pounds (332,100 kg) into the air, 102 pounds (46 kg) into surface water, and 96,000 pounds (43,500 kg) into injection wells; 1,000 pounds (454 kg) was treated off-site, for a total of 827,300 pounds (376,100 kg). By 2006, releases were down to 561,803 pounds (255,365 kg). The states with the highest releases between 1987 and 1993 were Louisiana, Delaware, Ohio, Pennsylvania, and South Carolina.

Vinyl chloride released to the atmosphere exists in the vapor phase and degrades rapidly through gas-phase photochemical reactions with an estimated removal half-life of 1.5 days. It rapidly evaporates from shallow surface water at an estimated removal half-life of 0.8 hour to the atmosphere, where it breaks down quickly. In soil, vinyl chloride also evaporates quickly with a removal half-life of 0.5 day or less at depths shallower than four inches (10 cm). Evaporation is slower at deeper depths, and it is resistant to biodegradation under aerobic conditions. Vinyl chloride is highly mobile, and that which is not evaporated may leach quickly into the groundwater system, where it can undergo biodegradation under anaerobic conditions.

### ADVERSE HEALTH EFFECTS FROM EXPOSURE

Exposure to vinyl chloride can produce adverse health effects in both humans and animals. It mainly occurs in the workplace, near industry that uses or produces it, as the result of improper handling or through cigarette smoke, in which it occurs in small quantities. Acute exposure to vinyl chloride mainly affects the central nervous system, resulting in dizziness, sleepiness, and unconsciousness within five minutes, but recovery is quick when the source is removed. At higher levels, damage to the liver, lungs, heart, and blood system may occur, and it could be fatal. Dermal exposure will numb the skin and produce redness and blisters. Chronic long-term exposure to lower levels of vinyl chloride produces major liver damage,

nerve damage, and damage to the immune system. A generally very rare condition also results from exposure, in which blood flow is reduced to the hands, skin disorders develop on the hands and forearms, and the bones in the fingertips degenerate. Exposure can damage sperm and testes and result in reduced sexual function and irregular menstrual cycles. In animal studies, miscarriages increased and fetuses had reduced weight and delayed skeletal development with exposure, as well as an increase in cancer.

Vinyl chloride is designated as a group A chemical, human carcinogen. It has been clearly shown to increase the human occurrence of angiosarcoma of the liver, a very rare condition, and has been implicated in cancer of the liver, brain, lungs, lymphatic system, and the organs and tissues that produce blood. Animal studies support these findings with increases in both angiosarcoma and common liver cancer, as well as cancer of lungs, mammary glands, kidneys, skin, stomach, and Zymbal glands. Studies of cell cultures from humans, rodents, and other mammals exposed to vinyl chloride show genetic damage including mutations, deoxyribonucleic acid (DNA) damage, several types of chromosomal damage, and sister chromatid exchange.

### REGULATIONS ON HUMAN EXPOSURE

In response to these adverse health effects, federal agencies regulate the human and environmental exposure of vinyl chloride. The EPA drinking water standard is two parts per billion (ppb) or 0.002 milligram per liter of water, and all spills of one pound (0.45 kg) or more must be reported to the National Response Center. Exposure from consumption of organisms cannot exceed 2.4 ppb. The Occupational Safety and Health Administration (OSHA) has set a permissible exposure limit (PEL) of one part per million (ppm) in workplace air for eight-hour workdays and 40-hour workweeks. They further set a ceiling concentration exposure of 5 ppm for any 15-minute period throughout the day. The National Occupational Exposure Survey of 1981–83 conducted by National Institute of Occupational Safety and Health (NIOSH) found that 81,314 workers were exposed to vinyl chloride.

### volatile organic compound (VOC)

A VOC is a class of organic compounds that are primarily hydrocarbons and readily evaporate. There are literally thousands of VOCs existing as solids, liquids, or gases at room temperature. Methane (natural gas) is by far the most abundant and, as with many others, appears to pose no health risk to humans in normal air. Other VOCs such as benzene, formaldehyde, and chlorofluorocarbons do pose direct health or environmental risks. Benzene, for example, is an industrial solvent that is a known carcinogen, as are many other such VOCs. These evaporated or aerosol VOCs are primary pollutants. There has been much publicity of late about the abundance of VOCs in indoor air and the efforts to reduce it. There are many new restrictions on the amount of VOC in paints, sealants, and other household items. Many of the VOCs that are not direct health threats can undergo photochemical reactions in the atmosphere in strong sunlight with nitrogen oxides to form ozone and other compounds that are harmful to human health. These are secondary air pollutants. The U.S. Environmental Protection Agency (EPA) estimates that more than 19.8 million tons (18 million metric tons) of VOCs is released into the air over the United States each year, about 34 percent from transportation sources and 50 percent from industrial sources.

### TYPES AND USES OF VOCs

It is beyond the scope of this entry to list all of the VOCs. The more common EPA-regulated VOCs

include acrylamide, benzene, carbon tetrachloride, chlorobenzene, chloroform, DCA (1,2-dichloroethane), DCB (dichlorobenzene), 1,1- and 1,2-dichloroethylene, ethylbenzene, formaldehyde, MTBE (methyl tert-butyl ether), PCE (tetrachloroethylene), styrene, toluene, TCB (1,2,4-trichlorobenzene), and TCA and TCE (1,1,1- and 1,1,2-trichloroethane). They have a variety of household and industrial applications. They are used as fumigants (DBCP and EDB), gasoline oxygenates (MTBE), organic synthesis compounds (1,1-DCE and vinyl chloride), refrigerants (CFC-11 and CFC-12), and solvents (carbon tetrachloride, DCA, DCE, methylene chloride, PCE, TCA, and TCE). They are also integral parts of fuels (benzene, ethylbenzene, toluene, and xylene) and trihalomethanes (chloroform). Considering the wide variety of applications in this list, VOCs are virtually everywhere.

Although many people think of such chemicals as only affecting industrial workers, VOCs are also commonly found in the home and office. Household uses of VOCs include paints, paint strippers, wood preservatives, aerosol sprays, cleansers and disinfectants, glues and adhesives, permanent markers, correction fluids, copiers and printers, moth repellants, pesticides, air fresheners, stored fuels, automotive products, hobby supplies, dry-cleaned clothing, miscellaneous solvents, and many building supplies. Recent studies found that concentrations of VOCs in the home are two to five times higher than those found outdoors. It was further found that after the application of paint, sealant, or stripper, the concentrations reached levels of up to 1,000 times outdoor background levels and remained so for several hours.

### **ENVIRONMENTAL EXPOSURE OF VOCs**

With the heavy usage of VOCs in so many applications, it is no wonder that it occurs throughout the environment. Considering that they are volatile, release to the atmosphere is the overwhelming mode. They are primarily released from evaporation of fuel but also from industrial emissions, agriculture, and even home applications. Around urban areas, industrial plants, and military bases, and after pesticide application, there can be significant accumulations that range from temporary to more or less permanent. These concentrations can cause health concerns but pale in comparison to that from ozone. The tropospheric ozone that is ubiquitous around the world is almost exclusively produced by the reaction of VOCs with nitrogen oxides in the atmosphere. By far, this is the greatest threat from VOCs in the environment, and there are no signs that it will be resolved in the near future.

The National Water Quality Assessment Program of the U.S. Geological Survey conducted a study of VOCs in drinking water in the United States from 1985 to 2002. They sampled 3,500 wells in 98 major aquifers and analyzed them for 55 VOCs. The results were that 90 of the 98 aquifers tested positive for VOCs of some sort. Using a threshold cutoff of 0.2 part per billion (ppb), which is lower than the typical 0.5-ppb limit imposed by the Safe Drinking Water Act on the worst VOCs, 80 percent of the wells tested were within safe levels. Domestic wells were less likely to be contaminated (14 percent had VOCs) than public water supply wells (26 percent), but less than 2 percent exceeded the 0.5-ppb threshold. About 75 percent of the 55 VOCs were found in the 3,500 samples, but only about 15 were common. The most abundant was chloroform at 7 percent because it is a disinfection by-product of the chlorination of water. The second most common was PCE at 4 percent because it is used as a solvent by more than 80 percent of dry cleaners. Third most common was MTBE at 3 percent overall because it is an oxygenation component of gasoline. It was found in much higher concentrations in New England and the Mid-Atlantic states because there are more cars there, but because MTBE is no longer required in gasoline as of 2006, it should decrease in the future. The solvent TCE was the fourth most common at 3 percent not only because it is heavily used, but also because it is a breakdown product of PCE. Some fumigants such as DBCP were low overall but formed local concentrations where there was heavy use. In Oahu, Hawaii, for example, 30 percent of wells tested positive for fumigants. There were other smaller concentrations related to industrial use.

### **ADVERSE HEALTH EFFECTS FROM EXPOSURE**

Health effects from exposure to VOCs vary greatly depending upon the compound. Some produce very few effects at all but very high concentrations. The most common effects from short-term exposure include eye, nose, and throat irritation; and allergic skin irritation, headache, dizziness, loss of coordination, nausea, memory impairment, fatigue, and general intoxication. Most people recover relatively quickly when removed from the exposure. Sensitive people and those who have asthma can have much more severe reactions even at low concentrations that may require medical treatment. At higher levels, VOCs can cause damage to the kidneys, liver, and central nervous system. Long-term chronic exposure to VOCs at much lower levels can also produce these health effects, including significant brain damage. Some VOCs are carcinogenic,

producing a variety of cancers at various exposure levels.

**volcanoes** In addition to the utter devastation that volcanoes can cause purely through the force of eruption, they can cause levels of pollution of the atmosphere and surface of the Earth unequaled in a single event except that of an impact. Although the most impressive emission of a volcano is the glowing lava, it is insignificant compared with the volume of gases and particulate emitted in most subaerial eruptions. These emissions may be natural, but they are pollution, nonetheless, and may be even more damaging to the environment than anthropogenic pollution. They are capable of causing more radical climate change in a shorter period than all of the global warming caused by humans. Indeed, the success of humans over the past 10,000 years is owed in part to the lack of any large volcanic eruptions.

### AEROSOLS

There are two types of aerosols emitted during a volcanic eruption: particulate and liquid compounds. They can be released into the troposphere, where they directly affect humans, or they can be shot into the stratosphere, where they indirectly affect humans. In either case, the effects can be devastating depending upon the size of the volcano.

When a volcano erupts explosively, the emissions may be shot more than 10 miles (16 km) vertically from a summit eruption. The reason that they have such energy is that volcanoes along island arcs, such as the Aleutians, Caribbean, and Indonesia, or magmatic arcs, such as the Andes and Cascades, have a significant component of water incorporated into the magma. Some intraplate volcanoes such as the one at Yellowstone can also contain a lot of water. As long as the magma is under pressure, the water remains as liquid incorporated in it. This situation is analogous to the carbon dioxide in soda or beer, which remains in the liquid in closed containers. As long as the cap is on, no matter how much the bottle is agitated, it will not foam up. Release the pressure by removing the cap, and the carbon dioxide is released from the liquid as a gas. At standard conditions, a substance in the gas state will take up 22.4 times the volume the same amount will take up in the liquid state. For volcanoes, when the magma rises up the volcanic pipe, the pressure is released and the water and other volatile components convert to gas in an instant. At 1,768°F (1,000°C) or more, this instantaneous volume increase is hundreds to thousands of times, creating an explosion unequaled by the largest bombs.

### Stratospheric Aerosols

Large summit eruptions may shoot thousands of tons of aerosols into the stratosphere. The most common aerosols are ash, water, sulfur compounds, hydrochloric acid, and chlorine, depending upon the composition of the magma. Sulfur dioxide is typically the most plentiful and effective of the stratospheric aerosols. These aerosols can reflect back sunlight, preventing it from reaching the surface, thereby causing global cooling. The most famous recent eruption to produce such temporary climate change was the eruption of Tambora on Indonesia. In April 1815, this cataclysmic eruption emitted a column that reached a height of about 28 miles (44 km). It produced more than 36.6 cubic miles (150 km<sup>3</sup>) of solid particulate and delivered 200 million tons (182 million metric tons) of sulfur dioxide to the stratosphere. The volcanic cloud from Tambora spread over the entire atmosphere, and the sulfur dioxide reacted to form droplets of sulfuric acid. The reflected sunlight caused global temperatures to lower by as much as 5°F (3°C). Stratospheric aerosols are difficult to remove because there is no precipitation. Even a year after the eruption, most of the Northern Hemisphere experienced sharply cooler temperatures during the summer months. In parts of Europe and in North America, 1816 was known as "the year without a summer." Snow was reported

on the ground through June in New England and a worldwide famine ensued.

More recently, Mount Pinatubo erupted in the Philippines in 1991. It was a large eruption with a high column. Scientists estimate that Mount Pinatubo injected about 22 million tons (20 million metric tons) of sulfur dioxide into the stratosphere. The reflecting of sunlight cooled average global temperatures over the following year by about 1°F (0.5°C). There are many other examples of such cooling. These examples of minor cooling, however, pale in comparison to the potential eruptions. In comparison to the 36.6 cubic miles (150 km<sup>3</sup>) emitted by Tambora, Toba emitted more than 684 cubic miles (2,800 km<sup>3</sup>) 74,000 years ago, and Yellowstone emitted more than 610 cubic miles (2,500

km<sup>3</sup>) 600,000 years ago. The potential global cooling caused by an eruption of this nature could be catastrophic.

Aerosols also can produce chemical reactions in the stratosphere (heterogeneous chemistry). The most dangerous of the reactions are those that contribute to the destruction of stratospheric ozone and, thus, the ozone layer. The compounds most devastating to stratospheric ozone are those containing chlorine. Hydrochloric acid and free chlorine are not uncommon in certain eruptions.

### Tropospheric Aerosols

Many of the same materials that are incorporated in the stratospheric aerosols also appear in the troposphere. The difference is primarily in abundance

Block diagrams showing six most common types of volcanoes

but also the quantity and size of particulate. Gravity keeps the heavier particles closer to the surface, and they are the first to settle out. Pyroclastic material is volcanic particulate and classified by size and somewhat by shape. The larger fragments are called bombs and blocks (cobble and boulder size), lapilli (pebble size), and ash (dust size). The smaller sizes are the most common. Ash can spread out in the troposphere and be transported great distances before settling to the surface or being washed out by precipitation. Close to the volcano, it may accumulate enough to collapse weak structures. In most cases, it is just dangerous to breathe. Ash is primarily composed of volcanic glass fragments, especially pumice. It can cause silicosis and other scarring of the upper and lower respiratory system. If aircraft fly through plumes of ash, it is so abrasive that the engines can be destroyed, potentially causing a crash. It can also frost windows on aircraft and clog air intake vents. There have been several near-miss disasters of aircraft flying through ash clouds.

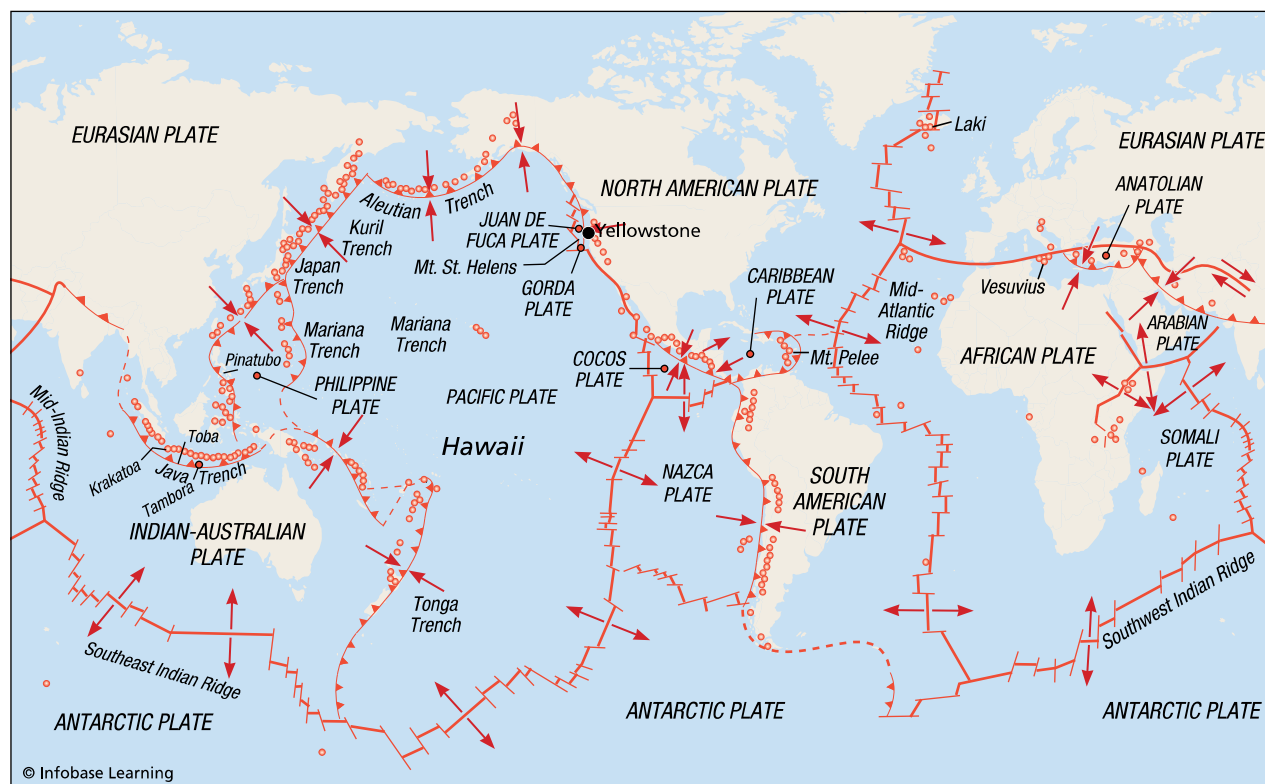

There is a huge number of chemicals emitted during the eruption of a volcano. A partial list of these chemicals includes sulfur dioxide, carbon dioxide, and carbon monoxide; numerous inorganic pollutants including lead, arsenic, chromium, cadmium, and mercury; and even organic compounds such as methane, benzene, and methylethyl ketone (MEK). Most of these compounds are in such small quantities that their contribution to the global pollution problem is negligible. Some chemical compounds, however, can be in quantities that can cause significant environmental problems to disasters.

The most common and abundant chemical pollutant from a volcano is sulfur. Through a series of reactions in the atmosphere, this sulfur is converted to sulfuric acid, which contributes to acid precipitation. The term *brimstone* refers to the sulfur that is emitted from a volcano, and many volcanoes are named for sulfur (Soufrière in the Caribbean, for example). For a single eruption, a large quantity of sulfur may be emitted but quickly dissipate in weeks to months after the event. In areas with prolonged volcanic emissions, however, significant acid rain may occur. In Hawaii, even though anthropogenic emission of sulfur is relatively low, there is a significant acid rain problem caused by the near-continuous volcanic emissions that must be monitored for health reasons. The Phlegraen Fields in central Italy also have had historical prolonged sulfur emissions. It is this area that served as the image of hell in Dante's *Inferno*. Other areas of extensive volcanic activity, as in Iceland, the Aleutians, and the Kurils, also have natural acid rain problems.

The June 1991 eruption of Mount Pinatubo, Philippines  
(AP Images)

In rare instances, other dangerous chemicals may be emitted in high enough quantity to present a problem. Light and volatile elements such as chlorine and boron are the most common. One of the best examples of this phenomenon was the Laki, Iceland, eruption of 1783. This eruption emitted basalt, which is usually relatively safe. This eruption, however, was the largest of its kind in historical times. It produced 3.5 cubic miles (14.7 km<sup>3</sup>) of lava, covering an area of 218 square miles (565 km<sup>2</sup>). Lava poured from the fissures at an astounding rate of 295,000 cubic feet (8,600 m<sup>3</sup>) per second. Accompanying the lava was a huge emission of fluorine gas that was deposited on all of the vegetation in Iceland. The fluorine poisoned all of the livestock that ate it, resulting in the deaths of hundreds of thousands of animals. The famine that ensued resulted in the deaths of 9,000 residents of Iceland, or 25 percent of the population at the time. A significant amount of the emissions remained in suspension over Iceland and all of

**Tectonic map of the Earth showing the major types of plates and many of the locations of known active and dormant volcanoes (circles)**

northern Europe for months after the eruption and caused a peculiar haze that was compared to fog.

## **Waikele Naval Magazine Lualualei Valley, Hawaii (1993–present) *Soil and Water Pollution***

The Waikele Naval Magazine artillery arsenal was a 500-acre (202-ha) section of the Lualualei Valley on the leeward side on the island of Oahu, Hawaii, that hosted weapons, war, and hazardous waste. Located northwest of Pearl Harbor, the broad, flat-lying plains of this fertile bottomland made it ideal for farming, ranching, and military operations. In 1930, the U.S. Navy began acquiring property in the Lualualei Valley from private owners and the territorial government. By the end of 1931, almost 8,000 acres (3,238 ha) had been purchased and earmarked for a new weapons storage depot, which opened in 1934.

During World War II, the Lualualei Valley served as the primary ammunition and materials storage depot for the Pacific theater for all three branches of the service. Today, the 7,500-acre (3,035-ha) Naval Magazine Pearl Harbor, or NAVMAG, contains 250 aboveground storage units that can hold almost 80,000 tons (72,575 metric tons) of ordnance. The 300 military and civilian employees who work on the base are responsible for the care and maintenance of the largest reserve of conventional and nuclear weapons east of the Korean Peninsula. As in any well-designed military installation, the weapon and ammunition storage areas are dispersed for reasons of security and safety. Within the Lualualei Valley, the West Loch and Waikele subareas, or extensions, support the facility's overall mission. West Lock serves as the valley's main ocean shipping and receiving dock, as well as hosting the navy's Undersea Warfare Center.

## **THE POLLUTION AND CLEANUP**

The 500-acre (202-ha) Waikele extension, or “branch,” storage area is largely undeveloped, with a topography that consists of a level upland, separated from a lower, more eroded lowland by a steep cliff or bluff. A steep, well-maintained road connected the upland, which housed the entrance, administrative areas, barracks, and other support facilities, to the lowland, where weapons storage, transfer, and operations took place and where 20 tunnel magazines are carved into the cliffs of the bluff to protect them from air attack and to reduce the chance of a catastrophic explosion. Waikele is an inactive site, decommissioned in 1993 and declared surplus property. After more than 50 years of operation, however, environmental studies identified a number of areas where chemicals and munitions residue might have been released or disposed of on the property. To address potential public health and ecological impacts from these areas, the navy is currently in the process of remediating soil contamination at Waikele as part of its ongoing nationwide environmental program, managed by the Environmental Restoration Division of the Naval Facilities Engineering Command. This cleanup, performed in cooperation with both the U.S. Environmental Protection Agency (EPA) and the Hawaii State Department of Health, will allow the eventual reuse of the property. Five areas at Waikele are in the process of being remediated.

## **Firing Range**

Most outdoor firing ranges contain a row of paper, wood, or metal targets in front of a sand or earthen impact berm. The bullet passes through the target

and becomes lodged in or is captured by the impact berm. Lead is the preferred metal for bullets and other types of projectiles because it is heavy, inexpensive, and easy to mold or shape. Once the lead bullet, which is sometimes coated or jacketed with a layer of copper, penetrates the impact berm, it can pose a serious environmental risk. Lead can enter the ecosystem either as dust from physical abrasion through fragmenting or ricocheting or as mechanical and chemical weathering mechanisms begin to dissolve it and make the lead more bioavailable.

The small-caliber firearms firing range at Waikele is in the upland part of the site and its floor and impact berm contain extensive amounts of lead. Lead has also been detected in sediment samples from drainage areas downstream of the range. To address this contamination, lead-containing soil and sediment will be excavated and disposed of at an appropriately licensed off-island waste management facility. After postexcavation samples confirm

the removal of impacted materials, the area will be backfilled with clean soil.

### **Burn Pit Area**

This one-acre (0.4-ha) area of the Waikele lowland was the location where ordnance shipping containers were burned and other debris such as metal, glass, and concrete was discarded. Arsenic and lead have been detected in isolated areas (hot spots) in subsurface soil. These hot spots will be excavated and the impacted soil consolidated in a central location underneath a vegetative cover. Land use controls will be implemented for this area, which includes both a fence to prevent unauthorized access to the area, as well as a deed restriction that prevents its use for residential purposes and ensures that the vegetative cover will not be disturbed. The navy also will implement a long-term maintenance and monitoring program to maintain the integrity of the vegetative cover.

**A photograph of 1940 munitions storage bunkers at Naval Magazine Lualualei, Waikele branch, Waikakalua and Kipapa Gulches, Pearl City vicinity, Hawaii (Library of Congress)**

### Building 21

In this former vehicle maintenance and paint shop, use and surface disposal of spent chlorinated solvents and leaded paint sludge occurred. When they were poured down floor drains and used in weed control, they contaminated soil and groundwater in this area of the Waikale facility. The primary contaminant, carbon tetrachloride, is present in groundwater at almost 60 parts per million (ppm), well above the action level of 5 ppm. Ongoing monitoring indicates that the carbon tetrachloride is not migrating. The navy's proposed remedial plan for this area is to excavate and dispose of contaminated soil and to implement an enhanced natural attenuation remedy for groundwater. The enhancement is the injection of substrate to stimulate bacterial degradation of carbon tetrachloride and chloroform, its breakdown product.

### Underground Storage Tanks

Diesel fuel and gasoline were stored in 1950 vintage steel underground tanks in the upland area of Waikale. These tanks, which were removed in 1993, released petroleum hydrocarbons, including ethylbenzene, toluene, and naphthalene, into soil and groundwater at concentrations in excess of Hawaii Department of Health action levels. In response to the results of a pilot study, the navy plans to install a soil vapor extraction and bioventing system within the contaminated area. This remedial approach will expedite bacterial breakdown of petroleum hydrocarbons remaining in the subsurface at the site.

### Building 66

Building 66 was used as a battery storage and maintenance facility. Spent electrolytic fluids were poured onto a sloped area and contaminated underlying soil with lead. In addition, waste batteries were buried over a several-acre area near the building. The navy is carrying out an extensive excavation project to remove both the batteries and lead-affected soil. These materials will be disposed of at an EPA-approved facility on the U.S. mainland.

The remedial activities being conducted by the navy must balance several competing interests. They need to be protective of public health and the environment with a balance of costs against the risks posed by conditions at the site. They must also take into account the financial limitations of the navy's environmental restoration program budget. Finally, remediation planning must take into account the needs and desires of local residents, business people, and adjacent landowners. The navy's proposed actions will make the majority of Waikale avail-

able for reuse. This process, called in navy jargon a FOST: Finding of Suitability to Transfer, means that the property can be restored to civilian use, but that the navy retains responsibility to address contamination remaining at the site.

**war and pollution** Considering that war is meant to kill people, concern for the environment or public health during conflict is a very low priority. In terms of human casualties, it should be. For example, the D-day battle of World War II produced an immense amount of pollution. Bullets dumped tons of lead into Normandy beaches; bombs and other incendiary devices emitted phosphorus and sulfur compounds into the air and water; diesel fuel from ships and landing equipment spilled into the ocean; and fires and explosions released polycyclic aromatic hydrocarbons (PAHs) and many other chemicals into the air. Considering, however, that 5,500 young American men lost their lives, the number killed or having suffered to any degree from pollution is inconsequential. Even marine life suffered far more from the bombs exploding on the beach and in the shallow waters than it did from all of the pollutants. As Dwight D. Eisenhower, 34th president of the United States and commander of

the allied forces that went ashore on D-day, said in a speech on April 16, 1953:

Every gun that is made, every warship launched, every rocket fired signifies in the final sense, a theft from those who hunger and are not fed, those who are cold and are not clothed. This world in arms is not spending money alone. It is spending the sweat of its laborers, the genius of its scientists, the hopes of its children. This is not a way of life at all in any true sense. Under the clouds of war, it is humanity hanging on a cross of iron.

Some of the worst environmental disasters, however, are related to military action or its preparation, from the burning of the oil fields during the 1991 Persian Gulf War to the environmental problems at nearly every military base and military supplier in the United States.

### EARLY CONFLICTS

Even early conflicts were not environmentally friendly. Vegetation was trampled during battles, exposing bare soil. Removal of cover vegetation

increased erosion during subsequent rains and silted the local streams and ponds, producing a form of water pollution. In dry weather, open soil produced windblown particulate as air pollution. Invariably, settlements were burned, producing more air pollution, consisting of polycyclic aromatic hydrocarbons (PAHs), additional particulate, methyl ethyl ketone (MEK), and other pollutants depending upon what was burned. Later, fire was used directly as a weapon by employing wood, straw, and other vegetation and later using burning oil and other flammable substances. These advances further increased particulate emissions as well as the pollutants related to burning. Burning oil also added directly to soil pollution and later to water pollution in runoff after subsequent rainstorms. The partially burned hydrocarbons produced a number of pollutants, from PAHs to creosote and other organic pollutants, such as benzene or xylene, depending upon the type of oil. The environmental threat of these compounds in such high concentrations was not trivial.

Preparation for war was also costly to the environment. Once humans reached the Bronze and Iron Ages, smelting of ore to produce metals for weapons and body armor produced significant pollution in

Oil well fires set by retreating Iraqi forces burn outside Kuwait City in aftermath of Operation Desert Storm, 1991

the areas associated with mining and processing. Waste rock from mining operations polluted soil in the area, and subjecting fresh rock and ore surfaces to weathering greatly increased the amount of heavy metals in the soil and runoff. These heavy metals included lead, chromium, mercury, zinc, cadmium, arsenic, and others, depending upon the ore. Smelting operations greatly increased air, soil, and water pollution with heavy metals as well as sulfur, phosphorus, and other elements and compounds released from the ore. Fires used in processing also added particulate and organic pollutants to the air in quantities that could be significant. Considering the short average life span for humans during this time, it is doubtful that anyone even noticed that the metalworkers and others in those areas had shortened lives if they were, in fact, shorter.

Perhaps the first documented use of pollution as a weapon of war was in Carthage, North Africa. When Hannibal crossed the Italian Alps to face the Romans in battle in the first century B.C.E., he did not plan well and lost a significant part of his army including elephants to snow avalanches and exposure. This is because he attempted to cross in October rather than in summer. As a result, even though he gave the Romans a good fight and a better scare, he was defeated. He was forced to run a hasty retreat back to Carthage with the Romans close on his heels. When the Romans defeated Hannibal and took Carthage, in order to ensure that Carthage would never rise again, they plowed salt into the soil to make it unfit for agriculture. The salt was used as a chemical weapon. Similar use of salt took place in Spain and Portugal on the lands of convicted traitors through the middle of the 1700s.

### DEVELOPMENT OF CHEMICAL WEAPONS

Besides the salt and burning oil, humans continued to develop chemical weapons to increase their effectiveness in war. The Dark Ages in Europe saw only small advances, if any, but in China, the development of gunpowder changed the face of war forever. Once its effectiveness as a weapon was realized, gunpowder was widely produced and used. Mining and processing operations to obtain, refine, and produce sulfur, saltpeter, and charcoal and to mix them into gunpowder greatly increased pollution at those sites. The burning of gunpowder also produces smoke (particulate) that contains sulfur and organic compounds that pollute the air. After battles, this smoke hangs heavily over the battlefield and can be caustic. Given that large numbers of people lost their lives from the physical effects of gunpowder, namely, being struck with projectiles, concern for

this pollution was nonexistent. There was even less concern when lead was used for bullets even though the quantity added to major battlefields could be significant and last for centuries.

Just as with the earlier chemical weapons, hundreds of years passed before any real advances occurred. In the 19th century, the great advances in chemistry eventually made their way to the battlefield. The first chemicals introduced were medicinal, including drugs and anesthesia. It was not long, however, before chemicals were also used as weapons.

### World War I: The Chemical War

Chemical weapons were first widely used in World War I, and they produced horrifying results. It is estimated that some 88,500 people died directly from exposure to chemical weapons and another 1,240,850 were injured. The weapons were referred to as poison gas, though some were simply vapors from liquids. Even though they were greatly feared and caused the most hideous of deaths, they were not particularly effective, causing only about 4–5 percent of the total casualties and being easily rendered ineffective by weather conditions and later by protective clothing. The first chemicals used were various types of tear gas that were launched in shells. The idea was to incapacitate the enemy temporarily to make them easier targets for the infantry. Tear gas was used at the beginning of the war in the form of ethyl bromoacetate, first by the French on August 19, 1914, and then by the Germans on October 19, 1914. Neither of these early deployments was particularly effective; nor was the use of xylyl bromide (t-stoff) by the Germans on January 19, 1915. It was also relatively easy to avoid the effects simply by wearing goggles.

The first time chemicals were used to kill enemy troops directly was on April 22, 1915, when the Germans deployed chlorine gas against the French at Ypres, France. The chlorine was released from canisters and formed a green cloud that wafted over the enemy position. Chlorine is a powerful irritant that attacks the eyes, nose, throat, and lungs. It forms hydrochloric acid and other acids when combined with water that strip off the membranes in the affected areas. At high doses, it can cause pulmonary edema and death by asphyxiation. Early uses were especially effective because soldiers would try to outrun the cloud and thereby spend more time inhaling the chlorine as the cloud overtook them and they would inhale it more deeply into their lungs from panting. The canister deployment also proved to be a problem when at Loos, France, a chlorine gas cloud was blown back over British troops after they had released it. For that reason, gas began to

Trinity atomic bomb test site in New Mexico, July 16, 1945 (Los Alamos National Laboratory Archives) trinity-200

be loaded into shells for release directly in the enemy ranks. Chlorine gas was not used alone for long because it was found that simple masks were relatively effective at filtering it.

Later in 1915, the Germans began to use phosgene, a much deadlier chemical. Phosgene is a liquid below 47°F (8°C) but when heated becomes a gas that is four times as dense as air. To help it spread better, it was typically mixed with chlorine and loaded into canisters with a white star, thus its battlefield name. It is estimated that some 80 percent of the deaths from chemical warfare resulted from exposure to phosgene. The high density would allow it to hug

the ground and fill the trenches that characterized the battle tactics of World War I. Phosgene can only be smelled at high enough doses to cause irreparable damage, and even then it is easily mistaken for newly mown grass. At this point, it causes burning of the eyes and nose, blurred vision, difficulty in breathing, nausea and vomiting, lesions, pulmonary edema, and death of heart failure. The problem is that it is even deadly at lower than detectible concentrations. Soldiers could unknowingly be exposed to it and not show symptoms for up to two days. Then the same pulmonary collapse would occur and ultimately be fatal.

The most notorious of the chemical weapons of World War I was mustard gas, or sulfur mustard. Otherwise known as bis(2-chloroethyl) sulfide, mustard gas was first used by the Germans in September 1917. Mustard gas is a blistering agent that especially attacks any moist area. At high doses, it can strip away flesh to the bone. At battlefield doses, symptoms may not have appeared for two to 24 hours. At that point, headache and fever developed, and then the skin and mucus membranes blistered and were stripped away. Pneumonia set in, but death did not occur for four to five weeks. In the meantime, the victims were so wracked with pain that they had to be strapped to their beds. Anything touching their skin, even clothing or bandages, put them in agony. They were typically put on a bed beneath a tent made of sheets. Whereas most injured soldiers were stoic and quiet in the hospitals, mustard gas victims cried and groaned from the extreme discomfort. Luckily, by the end of the war, soldiers were so accustomed to gas attacks that they were equipped with relatively sophisticated gas masks and protective clothing, and gas attacks were less common. Deaths from mustard gas were far fewer than from phosgene or chlorine. On the other hand, mustard gas was determined to be a known human carcinogen, causing increased risk of lung and other respiratory cancers, by the International Association for Research on Cancer (IARC). More than 28,000 American soldiers were exposed to nonlethal doses of mustard gas in World War I and 15,000–60,000 soldiers were exposed for experimental purposes after the war.

The horror of chemical weapons was recognized by all participants of World War I. For this reason, they were banned in the Geneva Convention/Protocol of 1925. Chemical weapons saw minimal use in World War II and only by mistake, or so it was claimed. Nonetheless, the United States was producing 40,000 pounds (18,000 kg) of chemical weapons by the end of World War I and continued to produce and stockpile them until 1968. By then, it had accumulated more than 34 million pounds (15,400 metric tons). In 1997, the United States signed the Chemical Weapons Convention treaty, which required the destruction of all chemical weapons by 2007. In a statement made on April 7, 2008, the United Nations secretary general, Ban Ki-moon of South Korea, announced that more than 29,800 tons (27,000 metric tons) of chemical weapons in almost 3 million storage or delivery containers had been verifiably destroyed. Remaining stockpiles were expected to be eliminated by 2012. The 183 countries participating in the program represent 98 percent of the world's population.

Mustard gas was used in the 1936 Ethiopian War and in the 1984–88 Iran-Iraq War. Otherwise, its introduction into the environment from chemical weapons occurred only through leaks and spills from manufacturing, transportation, and storage. Phosgene, on the other hand, is used in the production of some plastics. In 2005, it was found that the amount of phosgene in the atmosphere was much higher than previously anticipated. Considering that phosgene contributes to the destruction of the ozone layer, this was not welcome news. Chlorine is widely used as a disinfectant and a bleaching agent. It is released to the environment on a daily basis from numerous industrial and residential sources. It is also highly toxic. These sources are unrelated to war, which only amplifies their negative effects on the environment.

### World War II Chemicals

Although chemical weapons were generally not used in World War II, there were other pollutants that were widely released. There was far more use of petroleum products for both transportation and weaponry. There was extensive warfare using ships, airplanes, tanks, trucks, and jeeps, all of which required gasoline or diesel fuel. With transportation mishaps, destruction of these vehicles during war, and vehicle exhaust, huge amounts of dangerous pollutants were released to the environment. Fuel was also used in weaponry in flame throwers in many campaigns and directly pumped into the cave systems of the volcanic islands of the western Pacific (Guadalcanal, Iwo Jima, etc.), where it was ignited. The gasoline used in flame throwers was mixed with a jellylike substance that was first derived from rubber but later a compound of naphthalene and palmitic acid called napalm. Bombs were more sophisticated and plentiful during World War II. Incendiary types of bombs included large amounts of phosphorus and napalm, among other dangerous substances. Napalm produces so much carbon monoxide that most people pass out near the explosion and are subsequently burned. It was heavily used in the Korean War as well. Pesticides including dichlorodiphenyltrichloroethane (DDT) were used to clear areas of disease carrying mosquitoes in swamps in several campaigns. The infrastructure of most countries had also advanced quite a bit after World War I. When chemical factories were destroyed during bombing missions, far greater quantities of much more dangerous chemicals were released to the environment. On the whole, there was far more pollution released during World War II than World War I.

Not directly used for battles but a well-used product nonetheless was Zyklon B, or cyanide, which

**Incendiary bombs being dropped from U.S. Army Air Corps B-29 Superfortress on Kobe harbor, Japan, June 1945** (AP Images)

fueled the gas chambers in the Nazi concentration camps. The Nazis crowded as many people as possible into small, tightly sealed rooms and then released a

tablet of Zyklon B, which vaporized immediately and caused a quick death by asphyxiation. Millions of noncombat civilians were executed in this manner and

burned in crematoriums. This atrocity, which includes the Holocaust as its major component, is certainly one of the darkest chapters in modern civilization.

Another chemical weapon that was developed during World War II was nerve gas. The problem with the gas weapons used in World War I was that soldiers could fight for a day or two before symptoms appeared. This lapse could be enough to win a battle or replace the injured soldiers. There was a need for a weapon that incapacitated troops immediately, and nerve gas was the solution. Although little was actually released during the war, much was manufactured. The first nerve agent was developed by accident in a laboratory that developed pesticides in Germany on December 23, 1936. This agent is called tabun (also known as GA) and was extremely potent on insects, but an accidental spill proved that it was also potentially lethal for humans. As was required by law, a sample was sent to the Nazi high command in May 1937. Once it was evaluated by the

German military, the entire research team was relocated to a top-secret research lab for the duration of World War II. The research team developed other nerve agents as well, including sarin in 1938, soman in 1944, and cyclosarin in 1949, otherwise known as GB, GD, and GF, respectively. The G refers to the country of origin (Germany) and the second letter refers to the order of the experimental compound.

Nerve agents are organophosphorus cholinesterase inhibitors that attack the nervous system of the victim. Normally, muscles contract and relax. Nerve agents inhibit acetylcholinesterase in tissues, resulting in excess acetylcholine, which does not allow the muscle to relax. Symptoms of exposure to vapor appear within seconds to a few minutes, whereas exposure to liquid may take up to 18 hours depending upon dose. Initial symptoms include runny nose, tearing, constricted eye pupils, and eye pain. They are quickly followed by blurred vision, coughing, excess salivation, tightness of the chest,

**Zyklon B (blue stains), a gaseous cyanide-based insecticide that was introduced into chambers such as this one in Majdanek, Poland, killed thousands of people during World War II. (USHMM, Archiwum Panstwowego Muzeum na Majdanku)**

and rapid breathing. As the cascade of events continues, the victim urinates, defecates typically with diarrhea, and becomes confused, drowsy, and weak with muscle spasms, headache, nausea, vomiting, abdominal pain, and irregular heart rate and blood pressure. Finally, the victim loses consciousness and has convulsions and paralysis before dying of respiratory failure. The entire sequence takes about two minutes to loss of consciousness and less than two more minutes to death.

The Nazis began plans for plants to produce nerve agents on a large scale as soon as they learned about their potency. A pilot plant was set up in 1939 and construction of a major plant was begun in 1940. As a result of the difficult nature of production, the plant did not become operational until 1942, and it remained in operation for 2.5 years before its capture by the Soviet army. There were more than 300 accidents including 10 fatalities even before the plant was opened. It is estimated that the plant produced between 10,000 and 30,000 pounds (4,545 and 13,636 kg) of tabun during the period. When sarin was invented in 1939, plans to build

plants for its production began immediately. Several smaller plants were operational and produced between 1,100 pounds (500 kg) and 10 tons (9.1 metric tons) depending upon the estimate. Sarin, tabun, and soman were loaded into artillery shells and readied for use against Allied targets but never used. There is evidence that the Nazis believed the Allies also had nerve agents and would retaliate if the Nazis used them.

The second group of nerve agents, called the V-series, were similarly developed by mistake, this time in Great Britain. Similarly to the G-series events, research on organophosphate compounds for use as pesticides was being carried out at a commercial laboratory. The first of these compounds was marketed as Amiton in 1954, but it was far too toxic for commercial use, and it was removed. The military took control of research on Amiton and renamed it VG, the V ostensibly for “venomous,” though the accuracy of the claim is unconfirmed. Other members of the V-series include VE, VM, and the most infamous, VX. The V-series of nerve agents have several advantages over the G-series in that they are about 10 times as power-

**Bombed-out Nuremberg, Germany, 1945.** The twin-spired Lorenz Church is in the distance, and a statue of Kaiser Wilhelm I is at right. (USHMM; National Archives and Records Administration, College Park)

ful and far more persistent. The United States entered the chemical weapon arena in 1958 when they traded information on the development of thermonuclear weapons with the British for their VX technology. By 1961, the United States had begun its own research and production program on chemical weapons.

The only real documented use of chemical weapons in war was the Iran-Iraq War of 1981–88, in which VX and tabun were used. Sarin was used in a terrorist attack in the subway system of Tokyo, Japan, in 1995. There are other reports of nerve gas leaks from storage facilities but none was major. The real threat of toxic gas may result from its mishandling. Until 1972, the military disposed of unwanted chemical weapons by dumping them into the ocean. They disposed of 32,000 tons (29,090 metric tons) of mustard gas and nerve gas in 26 poorly located dumpsites off 11 states on the east and west coasts. The U.S. Congress banned the practice at this point. The problem is that if the dumped steel drums leak, the nerve agent could persist for up to six weeks in the ocean, during which time it would kill every susceptible marine organism. It is suspected that part of the marked decline in marine life in the coastal United States may be the result of this leakage. The problem is that scientists have no idea whether the drums have leaked or by how much.

### Vietnam War

The Vietnam War relied primarily on conventional weapons. Therefore, most of the environmental effects were similar to those in previous wars. The main differences were in two areas, Napalm-B and Agent Orange. Although Napalm-B, or “supernapalm,” was invented much earlier than the war, it saw greatly increased usage. The *B* was added to the name because it no longer contained naphthalene or palmitic acid, but benzene and polystyrene instead. The burning of Napalm-B produces an abundance of partially burned hydrocarbons and carbon monoxide in addition to the usual by-products of petroleum burning. Agent Orange is a defoliant that was widely sprayed from helicopters and airplanes to increase visibility and speed of passage in the jungle. It was used from 1961 to 1971 before being banned. Its name derives from the color of a band on the drums in which it was stored. Agent Orange was at the center of a lawsuit by Vietnam veterans because it contains dioxin, which has been shown to cause various forms of cancer, among other problems.

### RADIATION AS A WEAPON

Radiation is probably the most deadly threat to the environment of all weapons and yet was one of

the quickest to progress from scientific discovery to weapon. Radiation was discovered in 1895 by the Curies, husband and wife, in France, and by the late 1930s, it was already being tested for use as a weapon. Radiation was only used directly as a weapon twice, both times by the United States and both times against Japan in an effort to end World War II with as little loss of life and scarce resources as possible. Radiation was used in the form of the atomic bomb (A-bomb), which was developed in the United States by a team of top scientists known as the Manhattan Project.

The Manhattan Project was the most concerted scientific effort to develop a weapon of all time. It involved the cooperation of British and American scientists in several top-secret laboratories around the United States. The effort had its roots in several prewar events. In 1934, Enrico Fermi, an Italian physicist and winner of the Nobel Prize in physics, conducted an experiment in which he was able to split a uranium atom, producing nuclear fission. This experiment was repeated in 1938 by German scientists just as Germany was claiming Czechoslovakia. When Germany invaded Poland in 1939, thus beginning World War II, great concern arose that Germany was developing a nuclear fission weapon in their laboratories. Separate projects in Britain and the United States were begun in 1939 in response, but neither was particularly effective. It was not until 1942, when General Leslie Groves, an army engineer who had just finished overseeing the construction of the Pentagon, assumed military responsibility for the project, that any significant advances were made. The project was named for the U.S. Army Corps of Engineers district in New York City and combined British and American efforts but excluded the Soviet Union. Scientific leadership was given to the American physicist Robert Oppenheimer, who immediately enlisted the help of the many prominent scientists fleeing Europe as well as those in the United States. He set up extensive laboratories throughout the United States and Canada to conduct this top-secret research. Some developed into small cities that remain today, including Los Alamos, New Mexico; Oak Ridge, Tennessee; and Hanford, Washington, all of which have significant pollution issues.

The first breakthrough in the Manhattan Project occurred on December 2, 1942, when Enrico Fermi produced the first self-sustaining nuclear chain reaction in a small laboratory under the stadium at the University of Chicago. The coded message from one of Fermi's colleagues, the physicist Arthur Compton, to James Conant, the chairman of the National Defense Research Committee, declared (in a very understated manner) the triumph of the experi-

ment by saying, “The Italian navigator has landed in the New World,” and this success began a race to produce a controlled reaction suitable for use in a weapon. Two methods to produce a reaction would emerge, one involving a gun-type assembly and the other involving an implosion assembly. The gun assembly involved shooting one subcritical mass of uranium 235 (U-235) into another mass to produce a supercritical mass that would undergo a fission reaction. The problem in the development of this bomb was separating U-235 from U-238 and determining the amounts needed to drive the reaction in a weapon. The implosion assembly involved the focused energy from high-explosive lenses on a plutonium core to initiate the chain reaction. Plutonium 239 does not exist in nature and must be produced by processing uranium 238 in a nuclear reactor. The challenges in this bomb were the separation of U-238, the converting of uranium to plutonium, and the determination of proper quantities to achieve critical mass. Both development efforts ran simultaneously and somewhat competitively.

The first nuclear test was carried out in the New Mexico desert on July 16, 1945, under the code-name Trinity. The bomb was a plutonium implosion device nicknamed “the gadget” that delivered an explosion with a blast equivalent to 19 kilotons (17,300 metric tons) of trinitrotoluene (TNT). Even the mightiest of bombs was dwarfed by this explosion. As a result of the success of this test, President Truman ordered the bombing of Japanese cities to preclude a lengthy invasion campaign, which would result in the loss of millions of lives. As a result, on August 6, 1945, the city of Hiroshima was destroyed by a uranium gun-assembly bomb code-named Little Boy, but Japan refused to surrender. On August 9, 1945, the city of Nagasaki was destroyed with a plutonium implosion assembly bomb code-named Fat Man. The blasts killed more than 100,000 people apiece outright, and nuclear fallout would kill tens of thousands of people from radiation sickness over the next several years. It is this unanticipated radiation that posed and perhaps still poses an environmental threat many years after nuclear testing has ceased.

Although the Manhattan Project was treated as top-secret, it did not escape spyings. President Truman was surprised when Prime Minister Stalin showed no concern at the announcement of the atomic bomb. The reason was that the information delivered by his spies allowed the Soviet Union to jump-start their own nuclear program. On August 29, 1949, the Soviet Union tested their own atomic bomb, code-named Joe-1 by the Americans. In those early days of the cold war, this development shocked and scared Americans enough that they rushed to

achieve dominance once again. The fear allowed a fringe of the Manhattan Project to achieve prominence. As early as 1942, it was recognized that nuclear fission could generate enough energy to initiate nuclear fusion, the process that powers the Sun. Enrico Fermi suggested that this process might lead to a “superbomb” but did not pursue it, as most of the Manhattan Project group did not favor devoting the time and energy. Edward Teller, a Hungarian-born physicist and close colleague of Fermi, however, continued to research the process against the wishes of his superiors. Even after the Soviet test, Robert Oppenheimer, the head of the Atomic Energy Commission, which succeeded the Manhattan Project, still did not favor development of a fusion bomb. He was overruled when on January 31, 1950, President Truman announced that the United States would develop a fusion, or hydrogen, bomb.

The program, led by Teller, was high priority and as such yielded quick results. The first hydrogen bomb was constructed in a project code-named Operation Ivy. The device, code-named Mike, was detonated on November 1, 1952, on Elugelab Island in the Marshall Islands. The device was more than 20 feet (6 m) high, weighed 140,000 pounds (63,636 kg), and yielded a blast equivalent to 10.4 megatons (9.5 million metric tons) of TNT, 450 times as powerful as the Nagasaki bomb. It obliterated the island and left a crater 6,240 feet (1.9 km) wide and 164 feet (50 m) deep. Although the products of fusion are less dangerous than fission products, in order to initiate the fusion reaction, a primary fission reaction is necessary. A fissionable jacket around the fusion fuel aids in the compression and heating. When the fusion reaction initiates, it obliterates the radioactive fission material into the explosion cloud. The environmental danger of this process was recognized on February 28, 1954, when the United States detonated its first thermonuclear weapon. The bomb, known as Shrimp, was detonated at Bikini Atoll, Marshall Islands, in a test that was code-named Castle Bravo. It delivered a blast equivalent to 15 megatons (13.6 million metric tons) of TNT that produced a radioactive cloud that covered 7,000 square miles (1,446 km<sup>2</sup>). A snowlike mist of nuclear fallout covered several islands, which had to be evacuated and are still uninhabitable, as well as a Japanese fishing boat—the *Lucky Dragon*. Crew members died; the contaminated fish actually went to market.

If there had been only a few tests, the potential environmental impact of nuclear testing might have been minimized. By the time of the Castle Bravo test, however, the Soviet Union had already conducted a thermonuclear test. On August 12, 1953, the device, code-named Joe-4 by the United States, was detonated. It was a relatively small blast, but by 1955

the Soviet Union had developed and tested a device that could yield megaton explosions. This is how the arms race began. The late 1950s and early 1960s saw numerous tests of ever-larger devices with nuclear fallout distributed worldwide by weather systems. This fallout settled on vegetation, into the soil, and into the water and was consumed by humans and animals throughout the time and beyond. The largest device was the Soviet Tsar Bomb, which was tested in October 1961 at 50 megatons (45.5 million metric tons) of TNT, which was a reduced load. In its full state, it would have yielded a 100-megaton (91-million-metric-ton) blast, which on its own could have significantly increased radioactive fallout.

All nuclear tests were either underwater or aboveground in the early days. In 1958, the United States, Soviet Union, and United Kingdom agreed to a test moratorium, but it was short-lived when the Soviet Union began testing again. In 1963, the Limited Test Ban Treaty, which eliminated the testing of nuclear weapons in the atmosphere, underwater, or in outer space, was signed by 116 countries. It did not limit underground tests, which were still conducted frequently. China, which was not one of the 116 participants, violated this treaty in 1992. In 1967, the United States, Soviet Union, and United Kingdom signed the Outer Space Treaty, which banned testing on extraterrestrial bodies. The 1968 Nuclear Non-Proliferation Treaty was signed by 133 countries and made permanent in 1995. The limiting and destruction of nuclear weapons began in the 1970s with the Strategic Arms Limitation Treaties (SALT), which were initiated because there was far more killing power stockpiled in nuclear weapons than there were people on the planet. There were three SALT treaties, two in 1972, which limited the number of antiballistic missiles (ABM) and intercontinental ballistic missiles (ICBM), and one in 1979, which limited payloads. Treaties that began in the late 1980s resulted in the destruction of a large part of the nuclear arsenal of the United States and Russia. The 1987 Intermediate-Range Nuclear Forces Treaty (INF) banned short- and intermediate-range missiles. The 1991 and 1993 Strategic Arms Reduction Treaties resulted in the destruction of a significant part of the nuclear arsenal in the United States and Russia. The 1996 Comprehensive Test Ban Treaty (CTBT) banned underground testing and established a monitoring network to enforce the ban, but the treaty was not signed by India, which continued testing. Currently, there are at least nine countries that have nuclear capability—the United States, United Kingdom, Russia, France, China, India, Israel, Pakistan, and North Korea—and possibly South Africa and Iran. Most have done significant testing.

### Waste Isolation Pilot Plant *Chihuahuan Desert, New Mexico (1999–ca. 2070)*

The world's first engineered repository for the permanent disposal of transuranic (TRU) radioactive and transuranic mixed wastes is located 26 miles (42 km) southeast of Carlsbad, New Mexico, in a remote part of the Chihuahuan Desert. Most TRU wastes are composed of protective clothing, tools, glassware, equipment, soils, and sludge contaminated by radioactive materials at nuclear weapon production facilities. Only defense-generated transuranic wastes can be shipped to Waste Isolation Pilot Plant, or WIPP. The 60-building WIPP complex in rural New Mexico represents the combined efforts of thousands of scientists and engineers working over a 50-year period at a cost of billions of dollars to develop a system to manage, store, and dispose of the nation's most toxic, defense-related radioactive waste safely. The facility is not permitted to accept high-level radioactive wastes or spent nuclear fuel generated from commercial power reactors. It is likely that those types of wastes will be shipped to Yucca Mountain, Nevada. Radioactive wastes are classified, described, and disposed of by using precise criteria.

### BACKGROUND

A 1957 National Academy of Sciences Report first recommended the disposal of radioactive wastes in salt beds or salt domes. These types of geologic repositories are particularly well suited for waste disposal for a number of reasons. They have good thermal conductivity and high radiation resistance. The salt readily dissipates the heat produced by the decaying radioactive isotopes, and its crystallographic structure tends to remain intact when exposed to high levels of radiation. Salt beds are relatively impermeable and are self-healing. Water does not readily enter or move through a salt formation because it becomes saturated and crystallizes new salt crystals. When a fracture forms or an open area is excavated, the salt recrystallizes to fill and heal the fracture or mined area and thereby can seal the radioactive waste from the environment. For the same reason, salt domes are commonly excellent oil reservoirs. The water and hydrocarbons are trapped and cannot escape to the surface or migrate around the salt beds.

In 1980, after an extensive environmental and site characterization program, the U.S. Congress authorized the Department of Energy (DOE) to establish a geologic repository in a salt formation in New Mexico's Permian Basin. This repository was designed to accept for permanent disposal of almost 6 million cubic feet (175,000 m<sup>3</sup>) of "contact handled TRU

waste" including materials with levels of radioactivity low enough so that they can be handled directly by workers using standard safety precautions and equipment. It can also handle approximately 25,000 cubic feet (2,323 m<sup>3</sup>) of "remote handle TRU waste," which includes materials with levels of radioactivity that require special, noncontact, or remote handling procedures.

Construction at WIPP began in earnest in 1983 and continues today. This site was chosen because it contains no circulating groundwater, is in a geologically stable area in terms of earthquakes and volcanic eruptions, and can be excavated deep enough to allow for a safety buffer of the same rock both above and below the designated disposal depth. It also helped that the Department of the Interior's Bureau of Land Management owned the land and the site had low population density.

The state of New Mexico bitterly fought the establishment and development of WIPP, but in 1996 Congress passed and President George H. W. Bush signed the WIPP Land Withdrawal Act Amendments, transferring ownership of the property to the DOE and withdrawing it from public use. Disposal of TRU wastes at WIPP takes place 2,150 feet (655 m) below ground in the 2,000-foot- (610-m-) thick Salado Formation, a salt layer deposited about 225 million years ago. The sparse desert rainfall (less than 10 inches [25.4 cm] per year) minimizes the amount of water that may infiltrate the waste.

### WASTE DISPOSAL

Four vertical shafts have been completed to the 2,150-foot (655-m) disposal depth, where there are seven disposal chambers or rooms, each measur-

Loading boxes of radioactive waste for disposal at the Waste Isolation Pilot Plant southeast of Carlsbad, New Mexico, 1999 (DOE Photo)

### RADIOACTIVE WASTE TYPE AND DISPOSAL

Waste Form	Description	Disposal
High-level waste	Spent fuel, concentrated liquid, or solid residuals produced by reprocessing spent fuel from commercial nuclear power plants. Nuclear fuel reprocessing is no longer done in the United States. Primary isotopes contained in high-level waste generally include cobalt 60, strontium 90, cesium 137, and iodine 129. A large nuclear reactor generates approximately 30 tons (27.2 metric tons) per year of spent nuclear fuel.	None available (Yucca Mountain, Nevada, being developed as a possible site)
Low-level waste	Low-level waste includes clothing, containers, animal carcasses, medical isotopes, depleted uranium, and other materials that have contact with radiation or are slightly radioactive. Accounts for 90 percent of all radioactive waste produced in the United States.	Commercial disposal facilities
Mill and mine tailings	Low-level radioactive waste that includes rock, sand, and other residues remaining after uranium, radium, or thorium has been mined. These high-volume, low-activity wastes contain about 80 percent of the radioactivity present in unprocessed ore.	Managed under DOE's Uranium Mine Tailing Remedial Action (UMTRA) Program
Mixed wastes	Low-level waste containing both hazardous and radioactive constituents. For example, scintillation fluid, in which a beta-emitting nuclide is dissolved in an aromatic solvent such as toluene, is a mixed waste.	Commercial disposal facilities
NORM—naturally occurring radioactive material	A number of earth materials contain radioactive materials that, if concentrated for commercial purposes, may pose a special health risk. Coal contains U and Th, as well as radium 210 and lead 210. Mineral sands are composed of titanium minerals, zircon (U-rich), and monazite, a rare earth mineral containing thorium. Tantalum concentrates used in the automotive and electronic industries are derived from pegmatite minerals, which contain U and Th. Phosphate rocks are used for fertilizer and contain U and Th. Oil and gas production residues contain radium 210 and lead 210.	Managed according to individual state regulations
TRU—transuranic wastes	Radioactive waste that contains more than 3,700 Bq/g of elements heavier than uranium (atomic number greater than 92). Artificially produced by the irradiation of nuclear fuel and most often associated with weapons production. Very radiotoxic because they decay by emitting high-energy alpha particles. Examples include plutonium and americium.	WIPP

ing 300 feet (91.4 m) long, 33 feet (10 m) wide, and 13 feet (4 m) high. The final facility design includes 56 rooms to hold about 850,000, 55-gallon (208.2-L) impact- and flame-resistant, high-integrity containers filled with TRU waste. Above-ground, WIPP's primary operations are centered at the 84,000-square-foot (7,804-m<sup>2</sup>) Waste-Handling Building, where containers of TRU wastes are unloaded, inspected, inventoried, and prepared for transport underground. Other support buildings include a health physics laboratory, exhaust filter building, emergency generators, and staff offices.

WIPP also operates its own fire department, ambulance, and mine rescue service. WIPP became operational in March 1999, and disposal operations will be ongoing through 2070. By 2006, WIPP had already received and permanently disposed of 5,000 shipments of TRU waste.

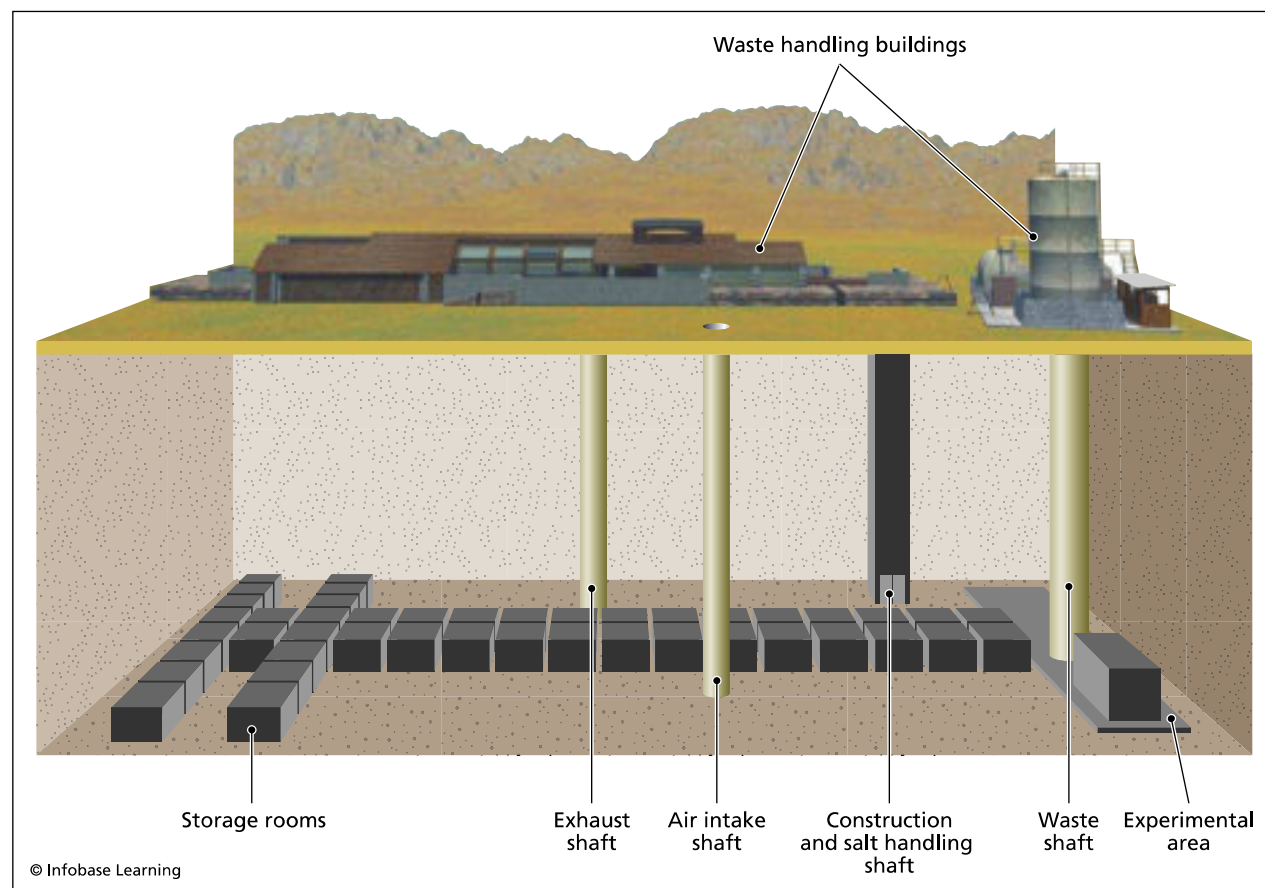

WIPP operations and TRU disposal are not without controversy or environmental risk. Because of their very long half-lives, transuranic wastes remain radioactive for thousands of years. WIPP has been designed to keep the waste isolated from the environment and people for more than 10,000 years. Facility

performance is based on a series of complex and sophisticated computer models developed specifically for the project that attempt to anticipate environmental conditions not decades or even hundreds of years into the future, but millennia. Whether these models are accurate, only our distant ancestors will know, although DOE has built in a number of design safety factors to try to account for future unknowns.

Perhaps the largest risk associated with disposal at WIPP is that related to inadvertent human intrusion. This part of New Mexico does have oil and gas and potash mining that is done in the vicinity of the plant. One potential failure scenario is the breach of disposal system integrity by someone drilling for oil or gas centuries from now, when land use controls at the repository site may have been forgotten or lost through deteriorating government records.

Water has been observed within the hollowed-out rooms, or panels, where TRU wastes are being placed for disposal. The presence of this water a half-mile (0.8 km) below the surface in the salt disposal layer raises questions about the long-term integrity of the waste containers because salt water corrodes most metals. Similarly, the possible inter-

action of waste and water, producing pressurized gases, could force radioactive material to the surface or into overlying water-bearing zones. The Salado Formation, however, is a relatively impermeable, stable geologic unit, which is isolated from groundwater by other impermeable rocks above and below it. The DOE thinks that the water in the disposal horizon was deposited with the salt or that it is water that has leaked down access and ventilation shafts or along old, improperly sealed boreholes that were drilled for oil and potash exploration purposes before WIPP was established. Site opponents disagree and interpret the water to show that the site is hydrologically connected to overlying and underlying water-bearing zones. So far, the DOE's extensive scientific analysis has been able to convince federal and state regulators as well as a large majority of the scientific community that water intrusion issues at WIPP are manageable and well within design performance parameters for the facility. There are nearly 30 sites around the United States that store TRU wastes in places ranging from outdoor pools to locked warehouses. Assembling those wastes in one central location that has been specially constructed

Cutaway subsurface block diagram showing the various components of the Waste Isolation Pilot Plant (WIPP) in New Mexico

and is heavily monitored is a sensible way to reduce overall public health and environmental risks posed by these very dangerous materials.

**water pollution** According to the U.S. Environmental Protection Agency (EPA), water pollution is the greatest threat and has caused the greatest amount of ecological damage of any form of pollution. It has not caused as many human casualties as air pollution events, but it has caused unparalleled damage to marine and aquatic life, birds, and ecosystems. The really devastating incidents of water pollution involve accidental and intentional spills of chemicals or fuels into surface water systems. Pollution of groundwater systems involves the leaching and downward movement of surface spills and leaks, leaching of surface applications of chemicals such as pesticides, infiltration of leachate from a landfill, and leaking of underground storage tanks (USTs), among others. Such pollution is typically not as immediately devastating as a spill but can have long-term effects on large numbers of people that may only be recognized in retrospect.

Water pollution can be divided into two general types, surface water pollution and groundwater pollution, depending on whether the release is purely on the surface or infiltrates the soil and enters the subsurface. Both surface water and groundwater pollution can be caused by identifiable point source

releases or large-scale nonpoint source slow releases. Although surface water releases can be ecologically catastrophic, groundwater releases tend to be much slower but can involve large amounts of pollutant. Surface water pollution can further be in marine environments or terrestrial environments.

### SURFACE WATER POLLUTION

There are many forms of surface water pollution and many cause serious problems. Unlike groundwater, surface water undergoes no mechanical filtering—input must rely completely on degradation by microorganisms, aeration, and exposure to sunlight. Some pollutants break down readily under these conditions, whereas others persist unhindered. Depending upon the volume of the spill or the frequency of small spills, the natural system may be quickly overwhelmed and ecological damage can result. In many instances, these two types of surface water spills have been devastating.

Surface water can be polluted in a number of ways. The large-volume spills are typically composed of undiluted chemical, which is mainly some type of fuel or petroleum derivative. These are primarily less dense than water—light nonaqueous-phase liquids (LNAPLs)—and thus float on the surface, largely affecting the top and edges of the body. Chemicals that are denser than water—dense nonaqueous-phase liquids (DNAPLs)—sink to the bottom and affect bottom sediments and bottom-dwelling organisms. Cleanup of such spills is usually a long and complex process with a high potential for errors and collateral damage.

Surface water is also polluted on an everyday basis both by accidental and deliberate low-volume spills and long-term processes. The release of pollutants can be from identifiable point sources and large-area nonpoint sources. By volume, most pollution is from surface runoff. Spilled oil and gasoline, pesticides and herbicides, fertilizers, road salt, and creosote from tar are just a few of the numerous chemicals that are swept into ponds and lakes or storm drains and transported into streams and rivers. The pollutants can be transported in aqueous form as mixed liquid, or they may be carried in suspension as particulate or attached to particulate.

Most heavy metal inorganic pollutants are of limited solubility and are physically eroded from soil and transported as particulate in suspension to and within surface water. Some organic compounds may attach to organic or clay particles in soil and may also be carried in suspension into surface water bodies. Both of these types of pollutants settle into the bottom sediments. While the inorganic pollutants

## CEMETERIES AND GROUNDWATER CONTAMINATION

The Paleolithic is that period of human history and development that began roughly around 2.5 million years ago and ended at around 10,000 B.C.E. with the advent of agriculture and fixed settlements or villages. During this time, humans evolved into their current body shapes. They learned how to use tools and survived by organizing into family-based clans of 50 or 60 people and following animal herds and foraging for edible plants. Toward the end of the Paleolithic, about 200,000 years ago, *Homo sapiens* began to emerge as the dominant humanoid life-form. Migrating from the African savannahs and quickly spreading across Asia, Europe, and the Americas, *Homo sapiens*'s larger brain, fully upright carriage, and capacity for complex thought and language gave this species a remarkable evolutionary advantage over their human cousins. Within 500,000 years of their appearance, no other humanoid life-forms were present on the planet.

### DEATH AND DISPOSAL OF DEAD BODIES

As *Homo sapiens* began to appear, so did the custom of burying the dead. Burial grounds and mounds dating back 200,000 years contain the remains of early *Homo sapiens* along with tools, clothing, and other indications that our ancestors disposed of their dead in a ritualistic manner. Burial in prehistoric times, as today, is done for a combination of reasons, both practical and spiritual. Upon death, with the cessation of its natural defense mechanisms, the body is almost immediately assaulted by a wide variety of decomposing bacteria for food and energy. Bacteria-induced decay of dead bodies results not only in the formation of foul-smelling gases but also in the spread of diseases. In actuality, according to a United Nations World Health Organization report, survivors of natural disasters are unlikely to become ill from contact with decaying bodies, and quick burial of the deceased may divert critical resources that should be spent in assisting the living in recovery efforts. Pathogenic organisms inside the human body such as *Escherichia coli* do not survive long once typical human metabolic functions cease, and the spread of disease after natural disasters is actually related to poor-quality drinking water, lack of adequate sanitation, overcrowding in refugee camps, inadequate medical care, and the lack of other critical infrastructure that may be missing or destroyed after a disaster. Health care workers, military personnel, and rescuers who have contact with dead bodies are at greater risk of contracting such infec-

tious diseases as hepatitis B, hepatitis C, human immunodeficiency virus (HIV), enteric pathogens, and *Mycobacterium tuberculosis*. Training and use of appropriate protective equipment, however, can minimize exposure risks.

Burial also prevents scavengers from devouring the body. On a more psychological or spiritual level, burial helps the family and loved ones of the dead accept the death and can reduce the sadness associated with it. In addition, many religions require burial as a condition of the deceased's having access to a pleasant and fulfilling afterlife.

### ENVIRONMENTAL EFFECTS OF HUMAN BURIAL

Human burial, however, has environmental consequences. In many Western countries, the concentration of dead bodies in belowground cemeteries, in combination with the chemicals used to preserve them, could result in serious groundwater contamination. Embalming is intended to protect or slow the process of decay. It is done to allow a period of mourning to occur without disruption by the physical biological degradation processes that would otherwise naturally occur. One of the earliest methods of corpse preservation was mummification, practiced by the ancient Egyptians as well by Inca and certain Peruvian cultures, most of whom believed that a well-preserved body would empower the dead in the afterlife. During the Crusades, crude embalming was done to allow the bodies of fallen noblemen to be shipped home for burial in a hygienic manner. As medical technologies developed, embalming chemicals became more sophisticated as embalmers borrowed and improved upon procedures and techniques used by biological researchers to preserve their laboratory specimens. The following summarizes some common burial customs.

#### 1. Christian

Embalming is permitted and the body usually is interred in a casket and placed in an above- or below-ground concrete vault or soil grave, depending upon local custom. In many traditions, the remains are buried face up, in an east-west direction, to view the coming of Christ on Judgment Day.

#### 2. Judaism

Embalming is not permitted and the coffin is constructed with no metal parts (wooden pegs instead of nails) to permit quick decomposition of the remains.

### 3. Islam

Embalming is not done and burial takes place in a cloth shroud without a casket so as not to delay decomposition. The face is pointed toward Mecca at the time of burial.

### 4. Hindu

Cremation is the preferred method, although some groups practice burial. Infants are more often buried than cremated. At the funeral site, in the presence of the male mourners, the closest relative of the deceased (usually the eldest son) ignites the funeral pyre. After cremation, ashes and fragments of bone are collected and eventually immersed in a holy river.

In the United States, embalming began to be widely used after Abraham Lincoln's death. His well-preserved embalmed body impressed the thousands who saw it as the corpse made its way via train across the country from Washington, D.C., for burial in Illinois. Finally, the basis for modern-day embalming technology was established in 1867 by August Wilhelm von Hofmann, a German chemist who developed formaldehyde, a chemical that was able to penetrate into the pores of the skin and tissue and preserve them without causing significant alteration in color or structure. Other embalming chemicals, mixtures of preservatives, sanitizers, and disinfecting agents, that have been used over the years include formaldehyde (5–30 percent) combined with methanol, ethanol, and other solvents. Arsenic had been used as an embalming agent, but it was banned in 1910 because of concerns that morticians could be sickened by its use or that cases of deliberate arsenic poisoning would not be detected.

In addition to embalming, burial practices in many cultures require that the body be placed in a coffin or casket to help isolate it from the environment and slow the rate of decay. The coffin or casket is placed, in turn, inside a concrete vault or burial chamber, which is intended to protect it from the crushing effect of the overlying soil. Both the coffin and vault slow but do not prevent the entrance of decaying microorganisms and water or their contact with the body. Both of these customs, embalming and coffin burial, while offering comfort to the living and protecting public health, also protect local environmental quality in the long term.

### GROUNDWATER IMPACTS

Infiltration of rainwater into and through the soil and the movement of groundwater are natural processes that affect buried remains. These infiltrating fluids

can interact with the remains, dissolve chemical compounds, and form a leachate that can interact with other water. Contaminants potentially associated with cemetery leachate include elevated levels of formaldehyde and other preservation chemicals, sulfate, nitrate, and pesticides (from landscaping operations), formalin chemical (also used in tissue preservation), elevated bacterial counts, and chemical oxygen demand (COD). Cemeteries often are located on well-drained local hilltops that serve both as recharge areas and as spring sources for many streams. Many are old, in use since the 1800s or earlier, and have provided ample opportunity for groundwater to have contact with embalming chemicals. It is surprising that there have been few documented cases of cemeteries' contaminating surface water or groundwater.

Arsenic detected in groundwater sampled down-gradient of a Civil War cemetery in Virginia may be related to arsenic-based embalming fluids used during the late 1800s. Other examples from the almost 100,000 named cemeteries in the United States are rare. This is because most people, even those who do not have a meaningful science or public health background, know better than to establish a cemetery in an area where leachate charged with embalming chemicals and bacterial decomposition products can degrade local groundwater supplies. Land use patterns also play a role in minimizing groundwater effects from cemeteries.

In urban areas, where burial densities are high, most communities are connected to municipal water systems, where supply sources are far removed from human and, in many cases, animal burial grounds as well as other contamination. In rural areas, people are well aware of the need to keep a safe distance between their source of drinking water and the decaying remains of their loved ones. For example, in Wisconsin it is illegal to drill a water supply well within 1,000 feet (331 m) of a cemetery. In parts of the country where water tables are close to the surface such as along the Gulf Coast, bodies are interred in above-ground vaults or tombs. St. Louis Cemetery 1 in New Orleans, commissioned in 1789, was one of the first cemeteries in the United States to utilize aboveground burial and is a popular tourist attraction.

Annually, burial of the dead in the United States consumes more than 30 million board feet (9.2 million m) of hardwoods (for caskets), 110,000 tons (100,000 metric tons) of steel, 3,000 tons (2,727 metric tons) of copper, 1.6 million tons (1.45 million metric tons) of

*(continues)*

(continued)

concrete, and almost 830,000 gallons (3.15 million L) of embalming fluid. Studies are ongoing to improve quantification of potential impacts on groundwater of embalming chemicals and the decay of casket materials. Recently, most mortuaries have switched from formaldehyde as the embalming fluid of choice to more environmentally friendly chemicals such as aardbalm, an iodine-based product.

As environmental awareness has grown, however, so has the demand for natural, or "green," burial. In this type of interment, the body is not embalmed, although it may be washed, disinfected, or religiously anointed. It is placed in a cloth shroud or a biodegradable box, not a wooden or metal casket or concrete vault, and placed in a grave in direct contact with the soil. All this is done to speed the process of decay and allow the remains to be absorbed or returned more quickly to nature. Natural markers such as trees and shrubs are planted to mark the gravesite, and neither pesticides nor irrigation methods are used to preserve the landscaping. Modern geolocating devices, such as global positioning systems (GPS), record and keep track of each burial plot. The open green established by these types of cemeter-

ies provides important, very usable ecological habitat and can serve as a wildlife preserve.

by Robert P. Blauvelt

do not degrade into another chemical, the organic compounds may be degraded by microorganisms if the chemical is not toxic to them. In contrast, soluble compounds dissolve into the water and exist in that form until they are degraded. Degradation may be by biological or chemical processes, or the chemical may simply evaporate from the water surface. Chemical degradation may be by oxidation at the surface, reaction with other chemicals in the water, or photolysis by exposure to sunlight.

Releases of pollutants into surface water can be divided into point source large-volume spills and nonpoint source long-term low-volume releases. The large-volume spills are commonly reported in the media and are ecologically devastating to a restricted area. The long-term low-volume releases happen imperceptibly but can cause global-scale problems.

### Large-Volume Spills

The most infamous type of large spill by its catastrophic nature and huge volume is an oil spill. Oil spills typically involve both human and wildlife casualties and are well reported in the media. The photos of these incidents can be quite spectacular. There are two main types of spill: those from production facilities through blowouts or sabotage and those from transportation accidents. Although transportation

incidents are more numerous and spectacular, the production facility spills are much larger and more serious. The 1969 Santa Barbara, California, blow-out and spill were galvanizing events in the early American environmental movement. The images of wildlife covered in oil and dying on television every evening turned the sympathy of the nation toward environmental concern.

Santa Barbara was a relatively small spill compared to the huge 1979 Ixtoc 1 spill in the Gulf of Mexico, but it occurred in the deep ocean in Mexican waters, and the slick took a long time to reach the Texas coast. This spill also caught the attention of the American public but not the way Santa Barbara did. Ixtoc released more than 3 million barrels (140 million gallons [532 million L]) of oil into the Gulf of Mexico; by comparison, in the Santa Barbara spill, approximately 3 million gallons (11.4 million L) of oil spilled into the Pacific Ocean. The 2010 *Deepwater Horizon* disaster had aspects of both Santa Barbara and Ixtoc I: It spilled a huge amount of oil into the Gulf of Mexico (204 million gallons [772 million L]) and captured the attention of the American public. It was the greatest environmental disaster in U.S. history.

The largest release of oil was caused by the 1990 Desert Storm oil fires in Kuwait. When American

troops invaded Kuwait to drive back the invading Iraqi troops, during their retreat, the Iraqis blew up as many of the wellheads from producing oil wells as they could. The result was a phenomenal conflagration and spill that would take months and the latest technology to control. It is estimated that the oil slick created by the release of an estimated 5.6 million barrels of oil (250 million gallons [50 billion L]) from coastal terminals and land-based oil wells contaminated a 300-mile- (483-km-) long stretch of beach. The oil was spilled through a combination of sabotage of the fields by the Iraqis, bombing, and a major battle site at a refinery. With so much oil in such a restricted area, it is estimated that the local ecology will never recover.

Spills during transportation occur primarily during shipment in tankers and supertankers; spills during transfer and from pipelines are less common and normally less damaging. There have been numerous accidents but none more infamous in the United States than the 1989 *Exxon Valdez* disaster. The supertanker *Exxon Valdez* hit a reef in Prince William Sound, Alaska, tearing a large gash in the hull and spilling 35,000 tons (10.8 million gallons [40.8 million L]) of oil into the pristine waters. The spill spread quickly to cover more than 900 square miles (2,300 square km) and caused great damage to the

fragile arctic ecosystem. As it turned out, the captain of the tanker was intoxicated at the time of the accident. This incident initiated great changes in the industry, especially with regard to tolerance of alcohol and drugs.

There were other incidents that were just as damaging, and many were handled just as poorly. The first accident with a supertanker was the *Torrey Canyon* spill off the southern coast of the United Kingdom in 1967. There was no protocol for tanker accidents, and numerous mistakes were made, the worst of which was to bomb the wreck with Royal Navy aircraft in an effort to sink the vessel and ignite the oil. There is still unexploded ordinance in the area today. Another example of igniting oil to remove the slick from a tanker spill was the 1992 wreck of the supertanker *Aegean Sea* off the coast of Spain. Upon ignition, the slick became an inferno. Flames shot 164 feet (50 m) high into the air, and oil residues coated the Tower of Hercules, a 1,900-year-old Roman lighthouse that is still in active use some 1.6 miles (2.5 km) outside the city of La Coruña, Spain.

In addition to the numerous oil spills from tanker accidents, there have been many catastrophic chemical spills to surface water. One of the more recent and important examples occurred in Jilin, China, in 2006. An industrial spill on the Songhua River

**Illustration showing several types of point source (chemicals, dumps, sewage, industrial waste) and nonpoint source (sediment, pesticides, fertilizer, decaying plants) pollution that can affect surface water quality**

contained several organic compounds but was primarily benzene. The residents of Jilin could not drink tap water for several days, and many people became ill because of the fumes. The importance of this spill is that the Songhua River flows into Russia, and the spill created an international incident. Fortunately, the spill occurred in winter, and cold weather slowed and dispersed the pollutants, allowing enough time from the release until it reached the border to resolve the situation diplomatically.

No matter how impressive these catastrophic incidents are in terms of impact on the environment and public health, they pale in comparison to the long-term, low-volume releases in terms of both total amount of pollutant released and long-term effects.

### Long-Term Low-Volume Releases

By far, most surface water pollution is the result of multiple or regular low-volume releases over a long period. These releases are not generally dangerous individually, and the pollutants may be absorbed by the system, dispersed, or biodegraded before they become a problem. After numerous releases, however, the surface water system eventually becomes overwhelmed and becomes polluted. The pollution may be released by a single facility or multiple sources. In the case of the Hudson River, New York, the source was a single facility. The General Electric plant in Fort Edward and Hudson Falls, New York, manufactured capacitors using polychlorinated biphenyls (PCBs) in the process. PCBs are organic dielectric fluids that produce a number of serious adverse health effects in humans, including cancer. They dumped PCB-laden wastewater from manufacturing directly into the Hudson River. The U.S. Environmental Protection Agency (EPA) and General Electric Inc. estimated that about 1 million pounds (453,592 kg) of PCBs was released into the Hudson River system south of Fort Edward over the 30 years 1947–77. This 200-mile (320-km) stretch of the Hudson River is now the largest single area of a Superfund site in the United States.

The Cuyahoga River in Cleveland, Ohio, is an example of multiple sources of pollution affecting a single surface water body. There have been numerous manufacturing, storage, and transport facilities along the river within and near Cleveland for well over a century and a half. These companies regularly disposed of their solid and liquid waste by dumping it into the river. The slow-moving river became so choked with pollution of oil and debris that it regularly caught fire. Its first recorded fire occurred in 1868. Ironically, the most infamous fire occurred in 1969; it was ironic because the fire was not very big

and the city had already devoted funds to cleaning up the river. It occurred, however, when the environment had become a major concern among the American people because of environmental disasters such as the Santa Barbara oil spill.

## GROUNDWATER POLLUTION

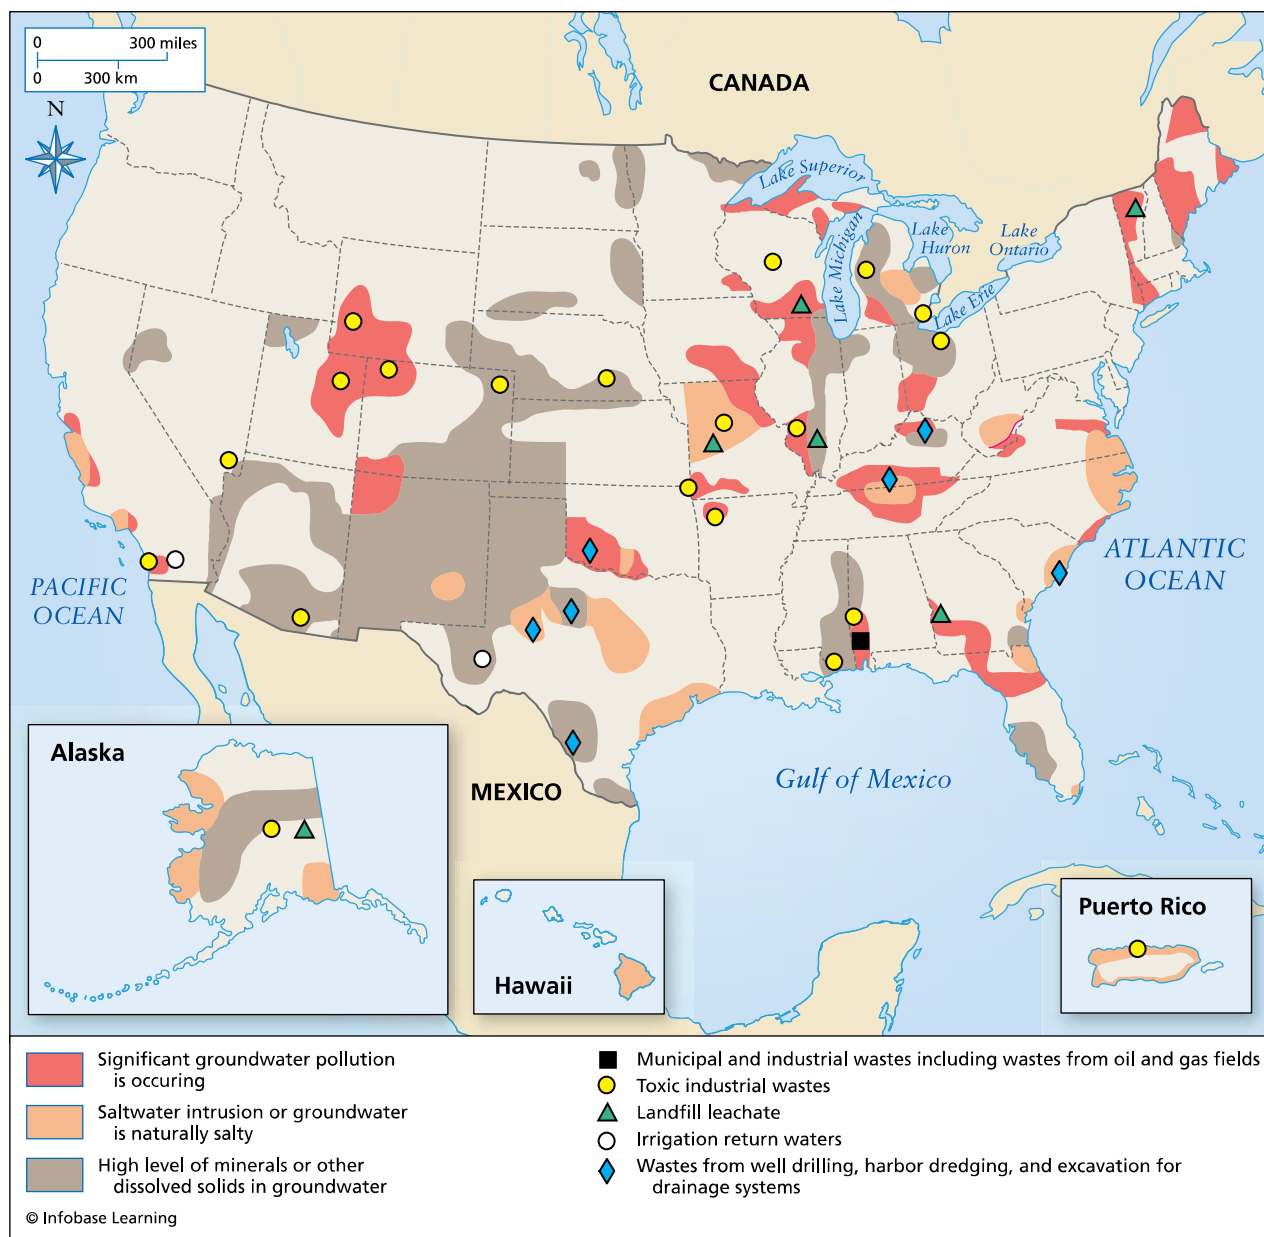

Groundwater pollution is primarily the result of leaking point sources, although there are situations when nonpoint sources may contribute to or even be the entire source. Pollution is also primarily the result of human activities, but in a few serious cases it is natural. It can also be a mix of the two. Groundwater pollution is usually dissolved into the groundwater and contained within rock or soil. The particles and water tend to dilute the pollutant to much lower concentrations than is found in surface water. The exception to this is in waste injection wells, where concentrated waste is injected as a slug directly into an aquifer. LNAPLs in groundwater tend to float atop the water table and remain relatively concentrated, whereas DNAPLs may mix with groundwater and become diluted more easily.

Certain geological configurations may also increase the concentration of the pollution. There is a configuration called bathtubting in which there is a bowl-shaped subsurface depression in an impermeable layer, most commonly clay. There is no flow of groundwater from the outside and, therefore, no migration and minimal dilution. If this depression is capped with a layer of clay, the pollutants can remain isolated from the environment indefinitely. If it is not capped, infiltrating meteoric water can overfill the depression, and the pollutant can rise to the surface and overflow the bathtub. Fractured rock aquifers can also become concentrated with pollutant by forcing out the groundwater. The fracture acts as a pipe, and if the pollutant is not soluble in water, it can provide enough pressure to expel the water and thoroughly replace it.

Although many environmentalists would rather blame all pollution on humans, a significant amount of groundwater pollution is natural. Certain pollutants can be natural while others have only human sources. They also have a completely different character in terms of source and dispersal. It is for this reason that they are considered separately.

### Natural Sources of Groundwater Pollution

In some cases, the natural rock and soil in an area can contain excessive levels of a pollutant. Certainly, mining prospects contain high concentrations of target metals or other elements, so the groundwater in the area will also probably be enriched. If the

**Map of the United States showing areas with significant groundwater pollution problems and the sources of that pollution**

target elements are heavy metals, the groundwater can be hazardous. Luckily, most heavy metals are not water-soluble and tend to be immobile unless the groundwater is quite acidic. These metal deposits are typically in crystalline rocks (igneous or metamorphic), and they are relatively restricted in extent.

One quite famous case of naturally occurring inorganic pollutants in sediments spread over a large area is in Bangladesh. Odd arsenic-rich sediments underlie large areas of the country. Prior to the 1970s, they were not a problem because most citizens employed surface water for personal use. The

problem was that there were frequent outbreaks of waterborne disease. The United Nations began an effort to eliminate the disease by encouraging the installation of tube wells for drinking water. It was only after this effort that the health problems began. The poisoning has been severe and has produced many serious adverse symptoms, including blackfoot disease, affecting large amounts of the population. It is estimated that 35–77 million residents of Bangladesh are at risk for arsenic poisoning.

A situation of enhanced natural groundwater pollution is occurring in New Jersey. In central and

southern New Jersey, residents draw their water from the sediments of the Atlantic Coastal Plain. Several years ago, during routine testing, several water samples tested positive for mercury. After a survey, a total of 600 wells were found to have elevated levels of mercury. The problem was that there were no nearby sources for the pollution such as landfills or manufacturing plants. With more detailed study, it was found that infiltrating water in the area was rich in residues of agricultural fertilizers. Apparently, when the infiltrating water encountered a common mercury-rich clay, exchange reactions released the naturally occurring mercury into the acidic groundwater. This example is really an interaction of natural pollution with groundwater pollution from humans.

### Groundwater Pollution from Humans

The natural sources of groundwater pollution are rare. Leaky landfills, buried waste, and underground storage tanks (UST) are far more common and dangerous sources. Perhaps the best example of polluted groundwater from buried waste is Love Canal in Niagara Falls, New York. The pollution was dumped into a bathtub configuration in impermeable clay by Hooker Chemical in the late 1940s to early 1950s. The pollutants included all of the most dangerous organic pollutants such as dioxin, polychlorinated biphenyl (PCB), trichloroethylene (TCE), pesticides, and numerous others. It was one of the largest repositories of hazardous waste in the world. The company installed a solid clay and ceramic cap, and there were no leaks for many years. The problem was that the city of Niagara Falls decided to develop the property. This situation might have even worked out well except that the city breached the cap when they installed sewer and water lines. The holes in the cap allowed precipitation to infiltrate into the toxic waste, and, as a result, it filled up the bathtub. Boils of toxic waste began appearing in the yards of residents, and children were receiving severe chemical burns while at play. When reports of the situation were on the evening news in the mid-1970s, Love Canal became the battle cry for the environmental movement and the new idea of the Superfund was born through attempts to address the problem.

Less dramatic and severe incidents of groundwater pollution are addressed on a daily basis by the huge environmental consulting industry. There are plumes of groundwater pollution from leak underground storage tanks (USTs) at gas stations and dry cleaning facilities in every state if not every town in the United States. Leaky septic systems and old landfills further degrade the quality. The shallow groundwater quality in virtually every urban area in

the country is so poor that it is not potable and often it is dangerous. In order to obtain clean groundwater in most areas, deep wells are required. The quality of water in America is in a near-crisis situation.

**waves** Ocean waves occur throughout a basin but are most noticeable at the shoreline. Driven by winds, they travel across the surface of the water. The greater the distance that the wind may act upon the surface, the greater are the resulting waves. This distance of interaction is called the fetch. Intensity of winds also determines wave height. Ocean waves form a sinusoidal pattern on the surface with all the features of those studied in physics. The peak of the wave is the *crest*, the bottom is the *trough*, and the distance between peaks or troughs is the *wavelength*. The height of the wave is the difference in elevation between the crest and the trough, and the amplitude is one-half of the height. The speed of the wave is typically measured in its *period*, which is the time it takes for similar points on two adjacent waves to pass a reference location.

Even though waves move consistently across a basin, the water in the basin generally remains in a fixed location regardless of the waves. In the open water, as a wave moves through, water particles move in a circular motion that is retrograde

to wave propagation. This means that as the wave approaches an area, the water is first pulled out to sea before lifting, falling, and returning to its original position as the wave passes by. This circular motion of the water particles is called an orbital, and they are larger nearer to the surface. The depth to which the wave penetrates is equal to one-half of the wavelength and is called the wave base. Below this, the water is still. Wave base constantly shifts up and down with the tides, being deeper in the basin at low

tide and shallower at high tide. It has a greater range during spring tide and the least range during neap tide. Wave base also varies seasonally with larger winter waves penetrating much deeper than gentler summer waves. Storm waves also produce a much deeper wave base.

As the wave approaches the shore, the wave base makes contact with the seafloor. The dragging of the wave on the seafloor slows it down, especially at the base. The wave begins to tilt forward and rise

Block diagrams showing shoreline processes as the result of the waves' approaching the shore and breaking at the beach

up. Successive waves crowd together as the result of the slowing. The orbitals of water movement flatten and the wave becomes asymmetric. It finally falls over in the breaker zone, and the momentum of the wave pushes the water up the shore face in the swash zone. It is the interaction of the waves with the seafloor that moves sediment. Gentle waves have shallow wave bases and do not have the energy to keep sediment in suspension. Sand can, therefore, deposit closer to the shore, and, in general, beaches grow wider in the summer as a result. In the winter, the waves are more energetic and have deeper wave bases. They can scour out sand and keep it in suspension. Energy is not low enough for deposition for up to several hundred yards offshore. In winter, sand is consequently removed from the beach and stored in offshore sandbars. There is a constant cycle as sand is slowly moved to the beach in summer and quickly removed to the offshore during the winter.

### LATERAL CURRENTS AT THE SHORE

Waves commonly do not move straight toward the shore but instead approach it at an angle. As a result, there is a net lateral movement of water parallel to the shore in the direction of the acute angle with the shore that is pushed by the waves. This lateral movement of water is called the longshore current, and it varies with the angle of approach. The more oblique the wave, the stronger the longshore current. This angle of approach typically only changes during storms, but in local areas it may vary with tides as well. As the wave approaches the shore, it drags on the seafloor and slows. The leading edge of oblique waves slows more than that part of the wave that angles out into deeper water. This difference in speed causes the wave to bend as it approaches the shore, a phenomenon called wave refraction. For shorelines that are not straight, the bending of the wave as it approaches the shore can be quite complex. In some cases, longshore currents can be driven toward each other, forming a temporary buildup of water. This built-up water is gravitationally unstable and escapes out to sea in a rip current, which can be dangerous for swimmers. It can also move large amounts of water and the accompanying pollution long distances away from the shore and out to sea.

### Littoral Drift

The longshore current typically transports sediment along the coast as littoral drift. The motion of individual sediment particles is not straight along the shoreline but instead resembles a sawtooth pattern. Particles move toward and away from the shore with each successive wave in addition to the lateral movement. Thus, the sand moves down the beach with

time. It is for this reason that beaches have been referred to as rivers of sand. Littoral drift can extend the length of a barrier island if the angle of the waves to the shore remains relatively constant. In this case, the barrier island continues to grow in length in the direction of the littoral drift. This growth can create problems if it crosses a channel or shipping lane.

If the angle changes abruptly or there is an obstruction, the sand may pile up in one area or be removed from another. Uneven coastlines typically have interspersed areas of sand buildup and starvation, which create difficulties for beach management efforts. The same problems arise when beach residents build jetties, piers, and breakwaters in front of their property. The flowing sand tends to be blocked by jetties and builds up on the side facing the littoral drift. The longshore current removes sand from the downflow side of the jetty, thus producing a sand deficit. As a result, shorelines with jetties have a scalloped appearance. Breakwaters are designed to reduce the energy of the waves reaching the shore. The reduction of energy allows sand to deposit behind the breakwater, where it normally would have continued to be transported by the longshore current. The beach slowly advances out to the breakwater, creating a spit of land. In simple cases, the littoral drift continues around the spit once it has formed. In complicated cases, the longshore currents can be changed, with potential to alter the whole sediment budget of the beach.

### SAND REPLENISHMENT PROJECTS

The combination of dams on coastal rivers, which reduce the sediment supply to the beach, and faulty beach management programs may cause a deficit of sand on certain beaches. Many beach communities rely on income from tourism to survive, so they must undertake efforts to replenish the sand supply. In many cases, the federal government is involved and funds the costly replenishment projects so the community is spared the cost. The sand that is stored in bars offshore during the winter may not fully return during the summer and over time accumulates there. The main replenishment technique, in this case, is to pump the sand back to the beach from offshore barges. In most instances, there is no problem with the practice unless offshore pollution is encountered by the barges. Then the pollution, whether dumped waste, ordinance, or settled chemical spills, can be placed in a location where people can have contact with it. There have been many serious incidents where medical and other waste has washed onshore, causing great concern. Old ordinance has also wound up in beach sediments. It is just a matter of time before one of these incidents turns into a disaster.

**wells** Any hole dug or drilled into the ground is a well. They can be as shallow as a few feet or as deep as 6 miles (10 km) or more. Wells can be used to test or remove water, rocks, and minerals or oil and gas. They are drilled using cable tools, which drive holes into the ground by repeated pounding of a weight if the well is in relatively soft, but consolidated material, and is relatively shallow (hundreds of feet). Rotary drilling rigs bore wells into virtually any kind of material and can extend to great depths (thousands of feet). There are a variety of bits on rotary rigs depending on the type of material to be drilled. They are capable of taking full-bore core samples of the rock and sediment that they penetrate, even in solid crystalline rock by using a diamond bit. Depending upon the material drilled and the depth, many wells must have casing set in part or all of the depth of the well. Casing is a sleeve or pipe mainly made of steel and must be cemented into place to seal the shallow fluids and sediments from entering the well bore. The most complex of these wells are for oil exploration and may take many months to drill and complete. In shallow wells, the casing may be plastic, cast cement, or ceramic. For environmental purposes, the most common wells are injection wells, monitoring wells, test or delineation wells, and recovery wells.

### TEST, OR DELINEATION, WELLS

Just as the name suggests, test wells are drilled simply to determine the subsurface composition or conditions. Test wells may be drilled to extract a sample of soil, gas, or fluid or to measure some physical or chemical parameters of it. For environmental purposes, they may help to delineate the extent of contamination from a source. In this case, a sample of fluid must be extracted by following a strict protocol.

**Diagram of a typical monitoring well used in a project to address an underground pollution problem**

Delineation wells are most commonly drilled to delineate an underground pollutant plume within an aquifer. They are drilled in stages, first to perform

a reconnaissance study of the degree of pollution and to determine the direction of groundwater flow. Once the preliminary study is complete, a drilling plan is established to define the problem best. The intricacy of the plan depends upon the extent of the plume, the sensitivity of the area around the plume, and the plume pollutant or pollutants. Larger plumes require more wells, as do areas that are environmentally sensitive or have dense human population. Hazardous wastes may also require special planning to minimize exposure of the community and workers. Delineation wells and the analysis of their results form an essential part of the remediation plan for the pollutant, the next step in the remediation process.

Delineation wells must also be drilled for subsurface soil pollution. In this case, there is no determination of groundwater flow direction to guide the drilling plan. Instead, drilling may have to be done in a grid pattern to delineate the pollution unless some other information on disposal is available. Such a drilling plan will show the areal extent of the pollution and at least part of the range of concentrations of pollutants.

### RECOVERY WELLS

Once a polluted groundwater plume is delineated, it must be remediated. In most cases, remediation can be done by pumping out the polluted groundwater and treating it once the source of pollution has been removed. Recovery wells continuously pump wastewater from the ground. Depending upon the size, extent, and migration of the pollutant, in some cases, a few wells or even one well may suffice. In the case of an extensive pollutant, a line of overlapping pumping wells can form a barrier to groundwater flow. The depth of penetration of the well or depth at which it is screened determines the horizon at which the water will be pumped and removed. There are many other configurations of well placement and screening levels to remove pollutants from the groundwater depending upon the plume and pollutants.

### INJECTION WELLS

Any well in which fluid or gas is driven down into the ground is considered an *injection well*. The most common injection wells function as waste disposal sites, and their driving mechanism is grav-

**Diagram that shows a gasoline leak from an underground storage tank (UST) migrating to the water table and releasing vapor into the soil gas (A) and a potential remediation method using two types of wells (B). The dewatering wells pump out the liquid and contaminated groundwater for treatment as well as lowering the water table in overlapping cones of depression. This leaves the gasoline in the soil, where it can evaporate, and the vapor is removed using an extraction well.**

ity. Probably the most common injection well in the past was a dry well. Attached to most old houses was a shallow (three to four feet [1–1.2 m]), typically rectangular well into which a drainpipe emptied. These wells were dug for “gray water,” wastewater from the bath or washing machine, to extend the capacity of the septic system with little danger of contamination. When the wastewater was drained into the dry well, the level was well above the water table and gravity forced the wastewater into the soil below the well, where it would be purified before infiltrating the groundwater system. If the homeowner was careful, the system worked reasonably well.

The same dry well concept was unfortunately also used in many small businesses and even in major industry. In small companies, a pit may have been dug on the premises into which all liquid waste was dumped. In a mechanic shop, old oil and solvents may have been dumped into a dry well only to pollute the groundwater in the area. Injection wells of this type cause severe environmental damage.

High-pressure injection wells are of various types for different purposes. Deep injection wells are utilized for burial of high-level waste at levels below the aquifers that provide water for public use. In the Rocky Mountain Arsenal in Colorado, high-pressure waste injection triggered earthquakes and had to be shut down. Other high-pressure injection wells are used to enhance fluid and gas flow around the wells. The high-pressure fluid fractures the rock around the well in a process called hydrofracturing. Both water wells and oil wells can produce higher yields as a result of this method. Even high-pressure gas can be used to fracture soils for the same purpose. This process is called pneumatic fracturing.

Injection wells may also be used to remediate pollutant problems. Chemicals and/or microorganisms may be pumped into the subsurface to address the pollutant. The microorganisms are used for bioremediation of the pollution problem.

**wetlands** After a history of considering wetlands a nuisance and draining and filling them whenever possible, today many communities and elected legislative agencies almost revere them. A number of laws and acts on the local, state, and federal levels have been passed to protect wetlands in numerous areas. The presence of wetlands formerly prevented development because they were too difficult and expensive to build on. Now they prevent development because they are considered to be ecological and environmental necessities. The biodiversity in a wetland and its position as the gateway between surface water and groundwater make them invaluable. Their ability to sequester carbon and toxicants that would otherwise be released to the environment and to store potentially usable fuel (peat) are other functions that are typically not even considered but add to their value.

Wetlands are areas of land that are inundated by water to a depth of one inch (1.64 cm) for at least several days in most years. There are three factors that determine the presence of wetlands: wetness (hydrology), the type of vegetation, and the type of soil. The most difficult of these factors to document is wetness because it can be so short-lived. The soils and vegetation, however, are characteristic and develop even if the area is wet for a short time. They are commonly used to determine wetlands even without the water. Wetlands have several

**Wetlands in British Columbia, Canada** (Vera Bogaerts; used under license from Shutterstock, Inc.)

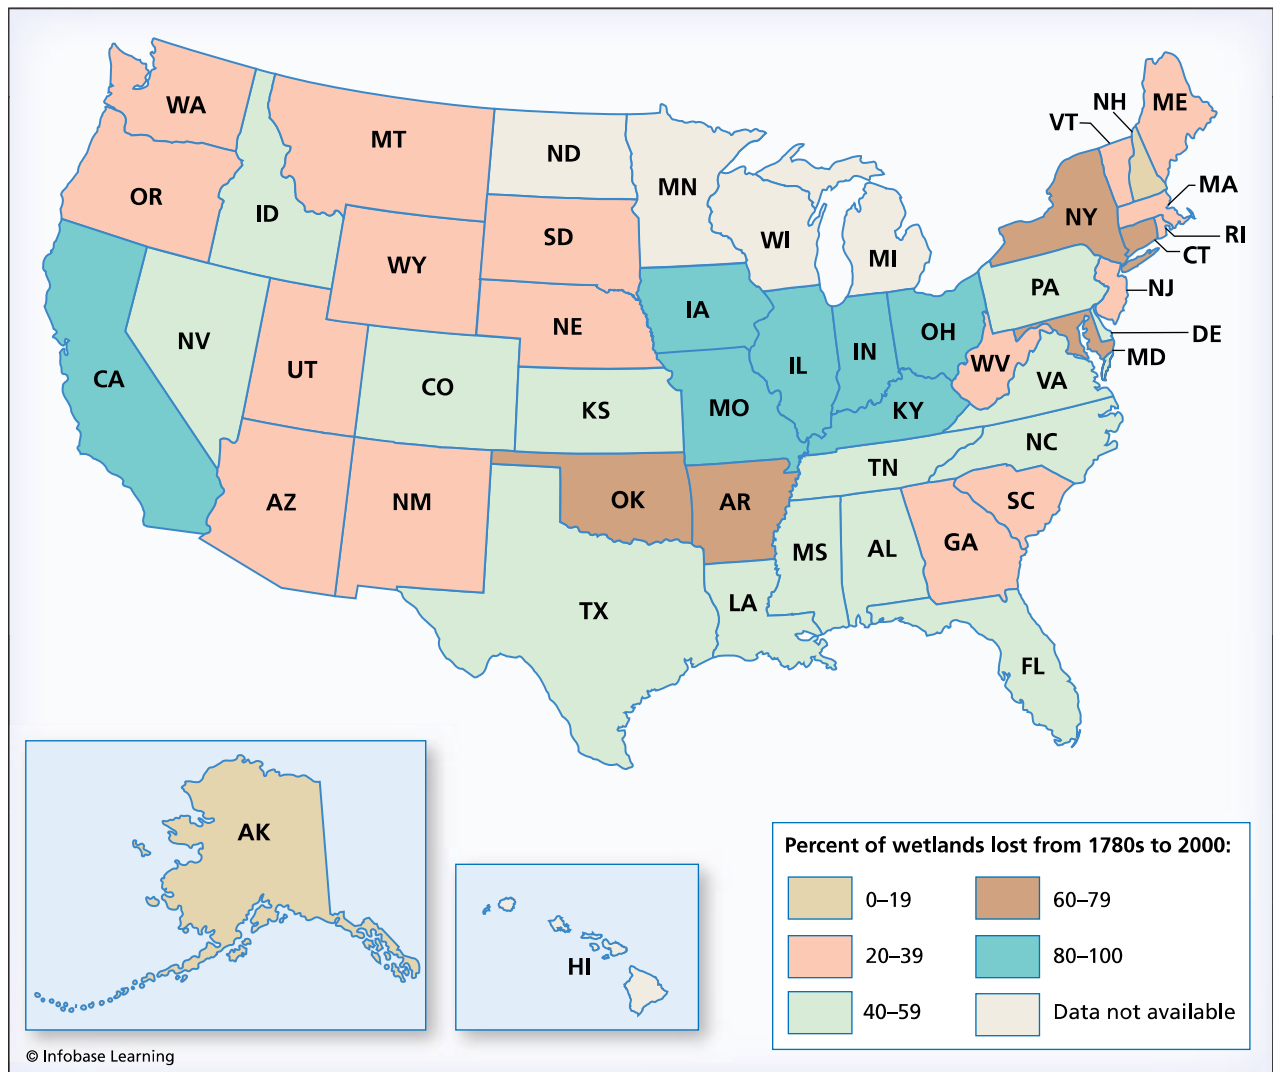

landscape features, including marshes, swamps, bogs, prairie potholes, and vernal pools, among others. Swamps and marshes are both frequently or continuously inundated by water; swamps have less flow. Bogs are wetlands that accumulate peat deposits through characteristic vegetation. Prairie potholes are small marshlike ponds, and vernal pools are shallow depressions that only occasionally hold water.

Wetlands and the ecosystems that they contain serve important environmental functions. Wetlands in coastal areas, salt marshes, for example, form buffers against coastal erosion by storm waves and floods. Plants in wetlands act as natural filters, trapping sediment, nutrients, and pollutants and preventing them from entering surface water supplies. Freshwater wetlands function as natural water storage areas during floods, thus reducing the severity

of downstream floods by allowing slow release of water. Wetlands are typically highly fertile areas, rich in nutrients and providing habitats for a variety of plants and animals. Freshwater wetlands often act as aquifer recharge zones, thus supplying groundwater to regions.

Coastal marshes are almost entirely protected by legislation in the United States. Freshwater wetlands are following suit in most areas but still threatened in many others. Approximately 1 percent of the nation's total wetlands is lost every two years and nearly all are freshwater varieties. It is estimated that about half of the total wetlands in the United States have disappeared in the past 200 years, including about 90 percent of all freshwater wetlands. They have been drained for agricultural purposes or urban development. Public concern over these losses has sparked efforts to restore nat-

Map of the United States showing the percentage of wetlands purposefully destroyed in each state between 1780 and 2000

**Diagram of constructed wetlands for the remediation of wastewater with input, left, and exhaust, right—a series of settling ponds/swamps remove pollutants through surface bioremediation.**

ural wetlands, but these projects are few, expensive, and not always effective.

In contrast, in some coal-mining areas, artificial wetlands have been constructed to reduce the effects of acid mine drainage cheaply and effectively. In these areas, vegetation that can tolerate high acidity and sequester inorganic pollutants is planted in a permanently wet catchment basin. The closed basin holds the pollutants until the plants can uptake them. The carbon sequestration capacity of wetlands may play an important role in reducing atmospheric greenhouse gases in the future. It is probably the easiest and most effective method of addressing the problem. As other uses of wetlands are identified for restoration of environmentally damaged areas, this practice may increase our wetlands in the future.

**Woburn wells G and H Woburn, Massachusetts (1983–present) Water Pollution** The pollution from the Woburn, Massachusetts, site was no more remarkable than that of many other polluted sites, but the situation is probably one of the best known among Americans. The reason is that the resulting lawsuit and the events leading up to it were popularized in both a book in 1995 and the 1998 film, *A Civil Action*. Although the location, names, and some of the facts were changed for the sake of protection of the victims as well as enhancement of the melodrama, the basic situation is preserved in the popular version. Some of the overlooked details, however, are interesting in their own right with regard to the pollution.

#### BACKGROUND

Tanning, as the process of turning animal skin into leather is commonly known, involves reacting collagen fibers in the hide, most commonly of cattle, sheep, or pigs, with a special chemical agent. Collagen is a type of tough, fibrous protein that is present in bone, cartilage, tendon, and other connective

tissues. In the United States, the most common tanning agents are trivalent chromium and vegetable tannins extracted from certain types of trees. Other agents, depending upon the intended use of the final product, include alum (potassium aluminum sulfate dodecahydrate, or potash alum), syntans, formaldehyde, glutaraldehyde, or heavy oils. Once absorbed into the hides' collagen, the tanning agent makes these and other types of animal skins moisture-resistant and keeps them durable and flexible for many years with only minimal care.

The tanning process can be divided into three steps. Beamhouse operations consist of receiving, trimming, and soaking the skins to make them pliable and removing unwanted hair or fur and tissue. This is done by a process known as liming, where the skins are dipped in a series of pits or drums containing calcium hydroxide. Once liming is complete, the treated skins are dehaired and moved to the tanyard, where an enzyme is applied to remove residual liming chemicals and to make the skins soft and pliable and receptive to the tanning agent. Pickling, soaking the hide in a brine and sulfuric acid solution to adjust pH prior to tanning, also may be performed in the tanyard.

The tanning step can take up to three weeks as the hides are soaked in progressively stronger concentrations of either vegetable or chemical tannins, which must fully saturate the treated hide. The skins are then wrung to remove excess tannins and then cropped or split and even retanned, if a particularly heavy or thick hide is being treated. Lignosulfate, corn sugar, oils, and specialty chemicals may be added to the hide, to improve its appearance, dura-

bility, or texture. The leather then is stretched and allowed to dry or may undergo additional chemical processing such as fat liquoring, which replaces some of the natural oils lost during tanning. The finishing process can include buffing the leather to produce a suede finish; waxing; shellacking; applying pigments, dyes, and resins for smoothness; polishing for a desired color; or lacquering with urethane to make glossy patent leather. Many leathers are treated with water- or solvent-based finishes and glued or attached to another fabric or material.

As might be expected, the use of both mechanical processing operations of scraping and trimming and chemical treatment can result in the generation of large amounts of hazardous and nonhazardous residues. Typical waste products from leather treating and manufacturing operations include spent and dilute organic solvents, particularly trichloroethylene (TCE), from fat-liquoring, drying, and soaking; ammonia from wet processing during deliming and dehairing, or if ammonia is used to aid dye penetration during coloring; and chromium from use as a tannin in soaking and drying and from the buffing process. Leather-making facilities can also emit a particularly obnoxious smell, a combination of rotting flesh and sour chemicals that has traditionally relegated them to the outskirts of town.

In addition to all the other needs a manufacturing business has, such as proximity to markets and transportation centers, a steady workforce, and inexpensive, available land, a tannery requires large quantities of freshwater. Tanneries, especially high-volume or production-type operations, use water in almost every step of their operation, from cleaning hides to rinsing finished goods, and a reliable supply is essential to a smoothly functioning business. In Massachusetts, just 10 miles (16 km) north of downtown Boston, the city of Woburn seemed an ideal place for a tannery, as well as other types of industrial manufacturing activities.

Woburn (2000 population of about 37,000) is an industrial center in central Massachusetts on the Aberjona River, a six-mile- (9.7-km-) long watercourse that has been described as one of the most heavily urbanized in the Northeast. Largely channelized, the Aberjona River flows southward from Reading through Woburn and empties into the Mystic Lakes, a one-time public water supply. Close to the major markets of Boston and with plenty of freshwater available, Woburn, by the middle of the 1860s, had more than 20 tanneries and currying (leather treating) facilities, all of them using the Aberjona as a water supply and sewer. By the 1870s, water quality in the river had deteriorated to the point that the Massachusetts legislature banned the discharge of wastes into one of its

**Smokestack at the former Industri-Plex chemical plant in Woburn, Massachusetts, ca. 1996** (Jim Davis/Boston Globe/Landov)

major tributaries (Horn Pond Brook), and, by 1911, outlawed discharges of wastes into the Aberjona itself.

### POLLUTION OF THE SITE

Despite these early attempts to improve Aberjona River water quality, local businesses and the city of Woburn continued to use the river both as a water supply and for disposal of sanitary and industrial wastewater, albeit in a much more controlled manner. In the mid-1960s, in an attempt to reinvigorate its declining industrial base, the city designated a 245-acre (98-ha) tract of land on its northern side, near the intersection of Routes I-93 and I-95, as an Industri-Plex. It was a specially zoned industrial area where manufacturing and other heavy industry would be encouraged to move and expand. With a long history of prior chemical and glue manufacturing in support of the local leather industry, the Industri-Plex site was gradually redeveloped throughout the 1970s and into the early 1980s and became home to paper, textile, pesticide (lead arsenate), and expanded leather-goods industries.

As development of the Industri-Plex went forward, the city of Woburn installed two additional water supply wells. In 1964, well G was drilled, and in 1967 well H was drilled. These wells tapped groundwater present in the interconnected fractures in the bedrock beneath the Aberjona River valley and could yield up to 2 million gallons (7.6 million L) per day. Periodically tested for bacteria and other basic water quality indicators, criteria it regularly met, water from wells G and H was piped into the municipal supply system without treatment. By the late 1970s, these two wells were supplying up to 30 percent of the city's water. Then, in 1979, while on routine patrol, police officers found 200 drums of waste solvent abandoned on a vacant lot near wells G and H. To their credit, they quickly realized that the presence of these drums might have adversely affected the groundwater quality, and they notified local health officials. Water samples were taken and laboratory results indicated that well water contained elevated levels of volatile organic compounds (VOCs), most notably trichloroethylene (TCE).

Later that year, two requests for assistance were made to the federal government's Centers for Disease Control (CDC). The first was by an official of the Massachusetts Department of Public Health, who noticed an increase in mortality rates for various cancers in Woburn and was investigating whether they were related to pollution from the facilities at the Industri-Plex. The second request was from a pediatric hematologist at Massachu-

setts General Hospital in nearby Boston. This doctor advised the CDC that he had evaluated six children with acute lymphocytic leukemia from Woburn, all living within a six-block radius of each other. A local clergyman later announced to the mayor and press that he had uncovered 10 childhood leukemia cases in one part of town that had developed over the past 15 years. The CDC later concluded that death rates in Woburn between 1969 and 1978 were statistically higher by 13 percent than in similar populations.

As the health studies were being done, the city of Woburn arranged for an alternate water supply, and the Massachusetts Department of Environmental Protection and the U.S. Environmental Protection Agency (EPA) began the laborious process of determining where the contamination had originated and who was responsible for it. They focused their attention on the Industri-Plex and found that six separate properties on the site were contributing contamination to the aquifer that supplied wells G and H.

### THE CLEANUP

The Industri-Plex site and several surrounding areas were added to the National Priorities List as a Superfund site on September 8, 1983. The 330-acre (132-ha) site includes former and more recent waste disposal areas as well as adjacent wetlands and the Aberjona River. Runoff from contaminated areas flowed through wetlands and accumulated in Aberjona River bottom sediments, which are contaminated with polycyclic aromatic hydrocarbons (PAHs) and heavy metals including arsenic, chromium, and mercury. The pollution was caused by a combination of accidental discharges and intentional disposal of waste materials on the property owned or formerly owned by the responsible parties: W. R. Grace, Unifirst Corporation, New England Plastics, Olympia Nominee Trust, Beatrice Foods, and Wildwood Conservation Corporation. Although initially reluctant to assume responsibility for the cleanup, these companies entered into a negotiated settlement with EPA for \$70 million to fund cleanup activities.

These cleanup activities include removal of aboveground waste materials including drums of solvent and PCBs, "hide piles" of unprocessed or off-spec animal skins, and other debris on the site, often for decades, as well as securing the site from public access. They also include excavation and removal of more than 200 tons (180 metric tons) of soil for off-site disposal, as well as treatment of other soil in place with chemical oxidation and vapor extraction technologies. Finally, the cleanup requires dredging and restoration of ponds and wetlands that became contaminated from overland flow of surface

runoff and capping of certain impacted areas to reduce the amount of contaminated runoff entering the ecosystem.

Groundwater is being collected and treated from each of the source area properties to reduce its potential to migrate and recharge the Aberjona River aquifer system. As of 2006, more than 300 million gallons (1,134 million L) of contaminated groundwater had been withdrawn from the bedrock, treated to remove or reduce contaminant levels, and discharged into the Aberjona River. Remedial activities at this Superfund site are expected to continue for many years.

### THE AFTERMATH

In what is one of the most tragic footnotes in the history of U.S. environmental pollution, in 1982, eight Woburn families whose children had died of leukemia filed a very highly publicized lawsuit against several of the companies they considered responsible for the contamination of wells G and H. One of the main issues under dispute was whether drinking TCE at the levels found in the Woburn well water could have resulted in childhood leukemia. Although there was some evidence of a connection, there was no broad scientific consensus that such a link could be made authoritatively. After protracted litigation, including a jury trial, they were awarded a modest financial settlement, one that could never replace or make up for the suffering and loss of their children. It was this case that was described in *A Civil Action*.

### World Trade Center Disaster New York, New York (September 11, 2001) Air Pollution

On the morning of September 11, 2001, two jetliners hijacked by terrorists were purposefully crashed into the North and South Towers of the World Trade Center within one hour of each other in Lower Manhattan, New York City. More than 2,800 people were killed directly by the attack, and victims were still being found and identified by deoxyribonucleic acid (DNA) through 2007. The Twin Towers, which had been the symbols of American trade and commerce, collapsed in a twisted mass of steel and other debris into a hole that would take more than a decade to fill. The horror, death, and destruction of the event captivated people's attention to the exclusion of any other problems. These attacks led directly to military action in Afghanistan and Iraq and a new heightened awareness and even fear of terrorism among Americans.

Behind these blazing headlines, however, the fire and collapse of each tower generated a dangerous mixture of toxic smoke and gas that enveloped hundreds of buildings and potentially affected the health of thousands of residents, emergency response personnel, and construction workers. It is estimated that 250,000–400,000 people were immediately exposed to a mixture of dust, debris, smoke, and various chemicals. The effects of exposure to the environmental fallout of the disaster will be felt for many years in the health of the numerous victims of the tragedy.

### BACKGROUND

The idea to build the world's tallest buildings on the 16-acre (6.5-ha) parcel within Vesey, Liberty, Church, and West Streets was originally planned

in the early 1960s to revitalize the area by David Rockefeller, chairman of Chase Manhattan Bank, and his brother, Governor Nelson Rockefeller. Built and operated by the Port Authority of New York and New Jersey, its construction began in 1966.

Five city blocks were closed and more than 160 buildings demolished to make room for the two 13.4-million-square-foot (1.27-million-m<sup>2</sup>), 110-story high buildings, which included a central landscaped plaza and a retail shopping mall, the largest in Lower Manhattan, with six basement levels and three subway stations. Some 3,500 workers toiled for six years to remove 1.2 million cubic yards (1 million m<sup>3</sup>) of soil and build one of the most recognizable symbols of New York and American capitalism. By 1972, both towers were open for occupancy. In 2001, 50,000 people worked in the buildings on a daily basis with tens of thousands of others either visiting or passing through the mall on the way to nearby buildings, including the Mayor's Office, New York Stock Exchange, and Federal Plaza. All of the original buildings in the complex were destroyed as a result of the 2001 terrorist attacks.

The destroyed buildings included One World Trade Center (the North Tower), Two World Trade Center (the South Tower including the observation deck), and Seven World Trade Center (a 47-story office building), all of which collapsed. Three World Trade Center, the Marriott Hotel, was crushed by the collapses of the North and South Towers. Four and Five World Trade Center (two nine-story low-rise office buildings) and Six World Trade Center (the U.S. Customs House, a seven-story low-rise building) were damaged beyond repair and later were demolished. More than 2,800 people died at the World Trade Center site, including 343 firefighters and 66 police officers, as well as the 148 passengers and crew on the hijacked planes, along with the hijackers.

The overwhelming number of responders to the disaster site included personnel from many federal, state, and local agencies, as well as from private organizations, and various other workers and volunteers. The agencies and organizations include the Agency for Toxic Substances and Disease Registry (ATSDR), the Centers for Disease Control and Prevention (CDC), the Department of Energy (DOE), the Environmental Protection Agency (EPA), the Federal Bureau of Investigation (FBI), the Federal Emergency Management Agency (FEMA), the National Institute of Environmental Health Sciences (NIEHS), the National Institute for Occupational Safety and Health (NIOSH), the National Park Service, the Occupational Safety and Health Administration (OSHA), the Public Health Service

Commissioned Corps, the Substance Abuse and Mental Health Services Administration (SAMHSA), the U.S. Coast Guard, the U.S. Marshals Service, the New York State Department of Environmental Conservation, the New York State Emergency Management Office, the New York State National Guard, the New York State Office of Mental Health, the New York State Department of Health, the New York City Fire Department (FDNY) and emergency medical services (EMS), the New York City Department of Health and Mental Hygiene, the New York Police Department (NYPD), the New York City Department of Design and Construction, the New York City Department of Environmental Protection, the New York City Department of Sanitation, the New York City Office of Emergency Management, the American Red Cross, and the Salvation Army. All these people who responded to the site were exposed to the contaminants unleashed in the disaster.

### POLLUTION OF THE AREA

As the North and South Towers collapsed, a plume of smoke and dust cascaded through the streets of Lower Manhattan and rose more than 1,000 feet (305 m) into the air. Survivors fleeing for their lives and emergency response personnel rushing to their aid were exposed to a pulverized mixture of plastics, metals, hydrocarbons, cement, and numerous other toxic materials.

One inventory of the debris pile, which reached six stories in height and took up several city blocks (commonly called Ground Zero), included 200,000 tons (181,437 metric tons) of steel, 1,000,000 tons (907,185 metric tons) of concrete, 600,000 square feet (55,742 m<sup>2</sup>) of glass, and untold amounts of paper, computers, desks, filing cabinets, cleaning supplies, electric cables, air conditioners, and the wreckage of the hijacked airplanes. Residues from these materials remained suspended, settled out, and were resuspended over the next four days by wind, emergency vehicles, and recovery efforts, until a soaking rain on September 16 finally stabilized the dust. It took until December 20, when the fires burning in the rubble were finally extinguished, for smoke and related combustion products to begin to dissipate.

Hundreds to thousands of chemical compounds were entrained in the dust and smoke from the collapse of these buildings and the associated debris fires. Most public health and epidemiological studies, however, have focused on five key materials as having the potentially greatest impacts on public health:

**Debris from World Trade Center awaiting forensic processing at Fresh Kills landfill on Staten Island, New York, City, January 2002** (Mike Segar/Reuters/Landov)

### Asbestos

Asbestos is a group of fibrous, naturally occurring minerals. It is an extremely useful industrial mineral because of its relative abundance, which makes it fairly inexpensive, and its fibrous nature, which allows it to be added or woven easily into a variety of products. Asbestos's strong resistance to heat and fire, as well as its general nonreactive nature, makes it ideal for use in high-temperature applications such as brake linings, gaskets, and ovens. One of the most common applications for asbestos was as a flame and fire retardant, which was its main application in the World Trade Center. Asbestos is commonly mixed into cement or sprayed as quick-setting slurry directly onto steel beams or structural supports. If the steel is bent, the coating flakes off and can be pulverized, as can the cement.

Exposure to airborne asbestos was the main public health concern after the 9/11 attacks. Asbestos was extensively used as a fireproofing agent in the construction of the World Trade Center buildings, and, although some had been removed over the 30-year life span of the complex, hundreds of tons remained in its concrete and on the coatings of steel support beams.

More than 12,000 samples of dust and debris were sampled and analyzed for asbestos by the EPA. Most of the data consistently indicated that outside air

measurements of asbestos were below public health standards and typical for urban air. The notable exceptions included analysis of samples that were collected close to and just after the attacks in defined "restricted areas" at Ground Zero and samples from within nearby apartments, where dust was able to settle and accumulate. The Fresh Kills landfill on Staten Island, where the debris was disposed of, also had asbestos levels above acceptable levels in some cases.

The inhalation of asbestos fibers has long been associated with health problems in asbestos miners and handlers. In 1989, the EPA banned most uses of asbestos because of concerns related to more widespread or general public health exposures. Health effects related to inhalation of asbestos include asbestosis, or scarring of the lungs caused by an acid produced when the body tries to dissolve the invading fibers; mesothelioma, a type of cancer of the lungs, abdominal cavity, or pericardium (the sac surrounding the heart); and other types of cancer including gastrointestinal, kidney, and liver. Long latency periods, often on the order of 10–30 years, are associated with the development of asbestos-related disease.

### Particulate Matter

Particulate matter (PM), also called aerosols (liquid) or smoke (solid), are small particles of material sus-

pendent in a gas. Once inhaled, the particle's diameter controls how it will be distributed within the body. Particulate matter larger than 10 micrometers ( $PM_{10}$ ) is usually filtered by nasal hairs or mucus membranes in the throat. It was these larger particles that were responsible for a condition among construction workers and response personnel known as WTC cough. These large dust particles were mostly pulverized fragments of alkaline and caustic concrete and fiberglass, which irritated throats and nasal passages.

Particles between 10 and 2.5 micrometers are most often trapped in the upper airways of the lung and do not represent much of a health risk to healthy people depending upon their composition. Particles with extreme pH, either acidic or basic, can cause scarring of the bronchial tubes, and conditions such as chronic bronchitis can result. Much of the dust at the World Trade Center site was pulverized sheet-rock, which is primarily gypsum, a sulfate mineral. It can be reacted to form sulfurous and sulfuric acid in the body. Other particles were composed of multiple compounds, some of which were organic compounds that resulted from burning jet fuel and plastic items such as polycyclic aromatic hydrocarbons (PAHs), which are known human carcinogens. At-risk people, including asthmatics, the very young and very old, and people with chronic obstructive pulmonary disease (COPD), may also suffer severe to even fatal reactions to exposure to this size of particulate.

Particles smaller than 2.5 micrometers ( $PM_{2.5}$ ) can penetrate deeply into the lungs, bronchi, and alveoli. They can be absorbed directly into the bloodstream with the gases necessary for life. Commonly in aerosol form, they can include numerous organic compounds that can be harmful or carcinogenic such as PAHs. These small particles have been linked to increased incidences of asthma, lung cancer, and other respiratory diseases, even premature death.

Those present at Ground Zero within four to eight hours after the collapse of the North and South Towers were exposed to very high levels of PM. By mid-October, however, PM levels in Lower Manhattan returned to levels typical of those for other areas of New York City.  $PM_{2.5}$  levels decreased rapidly with distance from Ground Zero and generally within three to 10 blocks from the WTC site, they were at or below ambient air quality values. The EPA concluded that PM may have resulted in an increased risk of chronic health problems for those most heavily exposed.  $PM_{2.5}$  concentrations, however, do not seem to pose a significant risk to those who remained farther away from the disaster site.

## Metals

Lead, chromium, and nickel were present in building materials and furnishings such as paint, cables, plumbing fixtures, desks, and chairs throughout the North and South Towers. Analysis of protected dust samples up to six inches (15.2 cm) thick from window ledges and building roofs indicated that individuals exposed to dust shortly after the collapse probably inhaled lead and chromium in excess of regulatory levels. The concentration of these metals, however, decreased rapidly within a few blocks of Ground Zero, and no nickel was detected at concentrations above background levels at any location. Although short-term exposures to the levels estimated from dust analysis were not likely to pose increased health risks to the general public, the effects of longer-term, lower-level exposures on unprotected emergency response personnel, construction workers, or nearby residents are not known.

Exposure to other heavy metals such as mercury, cadmium, arsenic, and zinc is not known but expected to be low.

## Dioxins

Dioxin is the common name for a class of more than 200 organic compounds made up of two benzene molecules connected to either a single or a double oxygen bridge. Chlorine atoms are attached to this very large molecule at one of eight locations. Dioxins are produced when organic material such as wood or paper is burned in the presence of chlorine, which can be present in plastics and cleaning agents. Classified as a known human carcinogen, dioxin can result in a disfiguring form of chloracne with exposure to large amounts.

Between September 23 and the end of November, as the fires continued to burn and smolder in the Ground Zero rubble, airborne dioxin levels increased to between 10 and 150 picograms per cubic meter, more than 1,000 times higher than those found in typical urban areas. Those most exposed to these elevated concentrations were construction and emergency response personnel working on the ground and breathing in the heavy, low-lying smoke. Somewhat surprisingly, the EPA concluded that despite these elevated concentrations, overall health risks associated with exposure to dioxin at Ground Zero were not significant. This is because the amount of dioxin taken into the body through inhalation is very small when compared with that taken in through its primary pathway, ingestion of foods containing dioxin. Additional, follow-up studies of the exposed individuals are ongoing.

### PCBs

Polychlorinated biphenyls (PCBs) are a class of organic compounds in which chlorine atoms are connected to a special type of hydrogen and carbon molecule. PCBs have been used in such varied applications as insulating fluids in electrical equipment, as heat transfer fluids, as hydraulic fluids, and in lubricating and cutting oils. They have also been used as additives in paint and pesticides. They are chemically stable and have a high flash point. This physical and chemical stability has contributed to their persistence in the environment and ultimate bioaccumulation in animals and people. By the late 1970s, the use of PCBs had declined greatly because of environmental concerns and increasing regulatory pressures, except for very specialized applications, such as in electrical capacitors and transformers. Health effects associated with exposure to high concentrations of PCBs are skin rashes and chloracne. Both the EPA and the IARC (International Agency for Research on Cancer), however, have classified PCBs as probable human carcinogens.

At the World Trade Center site, low levels of PCBs were found in smoke from fires that were burning building materials containing PCBs. The highest recorded concentration was 153 nanograms per cubic meter. Typical urban air contains PCBs in the range of 1–8 nanograms per cubic meter, and the permissible exposure level for American workers (Occupational Safety and Health Administration [OSHA] regulations) for PCBs is 1 milligram per cubic meter. By the middle of October 2001, all PCB samples had values consistent with typical urban air. The EPA concluded that there were no increased cancer or noncancer risks associated with this level of PCB exposure. Possible synergistic effects of exposure to low levels of PCBs, metals, and other World Trade Center–related airborne pollutants have not been quantified. It was not until January or February 2002 that ambient air quality in the vicinity of Ground Zero returned to precollapse levels.

### HEALTH EFFECTS ON WORKERS

Within 48 hours of the attack, the New York City Fire Department found that about 90 percent of its 10,116 firefighters and EMS workers evaluated at the WTC site reported an acute cough and gastrointestinal problems. Many slowly recovered from these effects, but others did not, and still others died of the effects. Some 46 percent of the responders continue to experience at least one pulmonary symptom and 52 percent still experienced ear, nose, and throat symptoms nine months after the attack. As of March

2004, 380 firefighters were no longer able to serve as firefighters as a consequence of respiratory illnesses they developed after WTC exposure. The risk of chronic respiratory problems such as reactive airway dysfunction syndrome, irritant-induced asthma, and WTC cough appears to be associated with intensity of the exposure, defined as the time of arrival at the site and duration of exposure. Residents of the area also experienced adverse health effects from more remote exposure. A study conducted between October 25 and November 2, 2001, showed that about 66 percent of nearby residents most frequently reported symptoms of nose or throat irritation, and about 47 percent reported a persistent cough.

### THE CONTROVERSY

Immediately after the disaster, the director of the EPA, Christine Whitman, released a statement reassuring the residents and workers that there was no apparent health threat from the dust and gases in the area. Mayor Rudy Giuliani made similar comments but with a bit less certainty. After it became clear that there was a significant health threat, something of a cover-up unfolded. The original findings by the EPA were downplayed by President George W. Bush's White House staff in an effort to prevent panic. The Whitman statement had been edited by the White House. Later, Whitman defended herself that the EPA did not have the authority to require rescue and relief workers to wear protective clothing and that it was the responsibility of New York City to monitor these details. The controversy escalated over the years after the disaster to the point of congressional investigations and final admission of the poor handling of the environmental and public health aspects.

Senators and representatives from the area successfully lobbied for allocation of \$12 million in December 2001 to establish the World Trade Center Worker and Volunteer Medical Screening Program run by Mount Sinai Hospital. This was the first program to track and monitor the health of 9/11 responders. The group later was able to secure an additional \$90 million to expand the number of workers and volunteers eligible. They also successfully lobbied Congress to restore \$125 million in additional funding for long-term medical and mental health monitoring and treatment. There are several agencies that are involved in this program. The Agency for Toxic Substances and Disease Registry (ATSDR) entered into a cooperative agreement with the New York City Department of Health and Mental Hygiene in 2003 to continue support of the

WTC Health Registry for five years of its planned 20-year duration. The National Institute of Occupational Safety and Health (NIOSH) awarded five-year grants in July 2004 to continue the FDNY and Mount Sinai programs, which had begun in 2001 and 2002. In 2010, the U.S. House of Representatives failed to pass a bill that would have provided extended health care coverage to thousands of September 11 first responders. The James Zadroga 9/11 Health and Compensation Act, named for a New York City detective who died of a respiratory disease attributed to exposure to pollutants from the disaster, could not garner the support for passage.

# X

**xylene** Xylene is one of the most widespread and widely applied chemicals in the United States. It is typically among the top 30 chemicals produced in terms of volume. As one of the BTEX (benzene, toluene, ethylbenzene, xylene) components of gasoline, it is used on a daily basis throughout the world. As such, it is consequently one of the most widely distributed organic contaminants. Xylene, which is also known as dimethyl benzene, Xylol, methyltoluene, and Violet 3, has both artificial and natural sources and is released as both point source and nonpoint source pollution. It is dangerous enough to human health to be regulated and monitored. Considering that it occurs in 844 of the first 1,662 U.S. Environmental Protection Agency (EPA)–designated Superfund sites on the National Priorities List, its monitoring and regulation are no easy tasks. This is among the highest percentage for any of the hazardous chemical pollutants. As a result of the widespread distribution and adverse health effects associated with it, xylene has been ranked the 58th most dangerous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

## PROPERTIES, USES, AND PRODUCTION

Xylene is an organic compound that is typically a mixture of three methyl group isomers, meta-xylene, ortho-xylene, and paraxylene, and may be referred to as mixed xylenes or total xylenes. Though their components may vary, mixed xylenes are commonly 40 percent m-xylene and 20 percent each of o- and p-xylene, with toluene and other compounds forming the remaining 20 percent. Xylene is typically a colorless, highly flammable liquid with a sweet odor that occurs naturally in crude oil and coal tar. It can also

be produced in small quantities from some plants and from forest fires or the burning of tobacco. The primary use of xylene is as a solvent and a substitute for benzene, which is less safe. It is primarily used in the printing industry, in rubber making, and for leather products, typically with benzene and toluene. It is used to synthesize many liquid chemicals including phthalic acid and isophthalic acid, among others, and solids such as plasticizers (phthalates), polyester film, fabric and paper coatings, and some fabricated items. As a solvent, xylene is used in paint thinner, paint remover, resin, varnish, paint, shellac, enamels, lacquers, rust preventative, rubber cement, agricultural pesticides, and industrial and residential cleaners and degreasers. It is also used to make additives for fuels. The industrial production of xylene was approximately 5 billion pounds (2.3 billion kg) in 1982 and increased to 6.84 billion pounds (3.1 billion kg) by 1993.

## ENVIRONMENTAL RELEASE AND FATE

Release of xylene into the natural environment results primarily from emissions from petroleum refining and the exhaust of gasoline and diesel engines and residential and commercial oil furnaces. These sources can be both point source and nonpoint source pollutants. Other releases are from industrial emissions, spills and dumping, and leaks and evaporation from fuel transport and storage as well as pesticide spraying. During the EPA Toxic Release Inventory program of 1987–93, approximately 4.8 million pounds (2.2 million kg) of xylene was reportedly released to the natural environment. Of this release, about 81 percent was to land and primarily from the petroleum refining industry. About half of

the total release during this time was in Texas, with far lesser amounts in New Jersey, Illinois, Indiana, Alabama, California, Michigan, Georgia, Virginia, and Washington, in decreasing order of release. In 2006, total reported industrial mixed xylenes release was 31,955,403 pounds (14,525,183 kg), making xylene one of the most widely released pollutants.

Xylene is a volatile organic compound (VOC) and, as such, evaporates readily. By far, the most common pathway of release is into the air, where the xylene quickly degrades through photochemical reactions with hydroxyl radicals with a removal half-life of one to 18 hours depending upon conditions. Xylene evaporates quickly from surface waters with a removal half-life for rivers and streams of about 3.2–29 hours depending on conditions. In ponds, it is a bit slower with a half-life of about 144 hours depending upon conditions. Otherwise, xylenes are relatively resistant to chemical reactions and do not biodegrade quickly. Xylene released to soil is relatively mobile and adheres to clay and organic material poorly, if at all. It evaporates quickly from the surface of the soil, but once it enters the subsurface, evaporation is slow and it may quickly leach into the groundwater system. Leaching is very quick in sandy soils and somewhat slower in clay and organic-rich soils. Some biodegradation takes place in soil and groundwater, but field tests have shown that it may persist from months to years.

### HEALTH EFFECTS FROM XYLENE EXPOSURE

Virtually everyone is exposed to xylene through everything from automotive exhausts to cleaners and solvents to cigarette smoke to industrial emissions. There are a number of adverse health effects that may result from this exposure. Acute exposure to xylene produces a variety of symptoms such as eye, nose, and throat irritation; and headache, dizziness, difficulty in breathing, respiratory failure, and pulmonary congestion, followed by death if the dose is high enough. Long-term chronic exposure has been shown to produce central nervous system effects such as confusion, loss of balance, memory loss, headaches and migraine headaches, and malaise. Other effects include abdominal discomfort, chest pain, fever, numbness in the hands, impaired lung function, electrocardiograph abnormalities, pulmonary edema, and liver and kidney damage. Animals exposed to xylene at acute levels have experienced muscular spasms, hearing loss, loss of coordination, and changes in behavior, as well as death if the dose is high enough. Long-term effects include damage to the central nervous system, liver, kidneys, blood system, lungs, and heart, as well as increased mortality

rate. Rats showed bone marrow and spleen damage. When pregnant animals were exposed to xylene, there was a greater incidence of low birth weight, birth defects, and delayed skeletal development, as well as developmental problems after birth such as poor motor coordination and spatial navigation. Xylene is not classified as a carcinogen (EPA group D) and does not appear to be, but, surprisingly, the full cadre of appropriate studies to render an evaluation have apparently not been performed.

### REGULATION OF HUMAN EXPOSURE

As a result of the adverse health effects and widespread distribution of xylene, federal agencies regulate human exposure. The EPA has set a drinking water limit of 10 parts per million (ppm) of xylene under the Safe Drinking Water Act. They further recommend that children not ingest water with levels of 40 ppm or more for periods greater than 10 days. Every spill of mixed xylenes or p-xylene of 100 pounds (45 kg) or more and every spill of m- and o-xylenes of 1,000 pounds (454 kg) or more must be reported to the National Response Center. The Occupational Safety and Health Administration (OSHA) set an exposure limit of 100 ppm in work area air for an eight-hour-day, 40-hour workweek. For peak exposure, the limit is 150 ppm for 15 minutes. The National Institute of Occupational Safety and Health (NIOSH) recommends the same exposure limit as OSHA as well as a short-term exposure limit (STEL) of 200 ppm for 10 minutes and an immediately dangerous to life and health (IDLH) exposure level of 900 ppm. According to the NIOSH National Occupational Exposure Survey (1981–83), some 2,145,039 American workers were exposed to xylene in the workplace.

## **Yucca Mountain Waste Repository Nye County, Nevada (ca. 2017– )** *Waste Pollution*

Probably the most studied piece of ground on planet Earth is a five-mile- (8-km-) long, 25-feet- (7.6-m-) wide, U-shaped tunnel carved into a ridgeline of volcanic rock in Nye County, Nevada, about 100 miles (161 km) northwest of Las Vegas. Yucca Mountain, or more appropriately, the Yucca Mountain Project, has been selected to be the final waste repository for all of the unusable nuclear fuel and discarded high-level radioactive waste produced in the United States. Approximately 90 percent of this waste will be spent nuclear fuel from commercial power plants, government research reactors, and U.S. Navy submarines and ships. These rods are made up of specially enriched plutonium and uranium that has decayed to the point where it no longer efficiently produces

enough heat to generate the pressurized steam that turns the electrical generating turbines in a nuclear power plant. The other 10 percent is high-level radioactive waste generated from the reprocessing of spent nuclear fuel. Both of these waste types are made up of radioactive elements such as strontium, technetium, and neptunium that have decay half-lives ranging from only a few years to millions of years. The proper disposal of these wastes, which are now stored at almost 80 sites scattered across 35 states, has become essential for reasons of both national security and long-term energy policy. If electricity from nuclear power plants is to play a role in meeting the growing demand for energy in the United States, and in reducing greenhouse gas (CO<sub>2</sub>) emissions, then a safe, secure repository for its waste products must be established.

**Tunnel boring machine entering access portal at Yucca Mountain, Nevada Test Site, Mercury, Nevada, 1994**  
(DOE Photo)

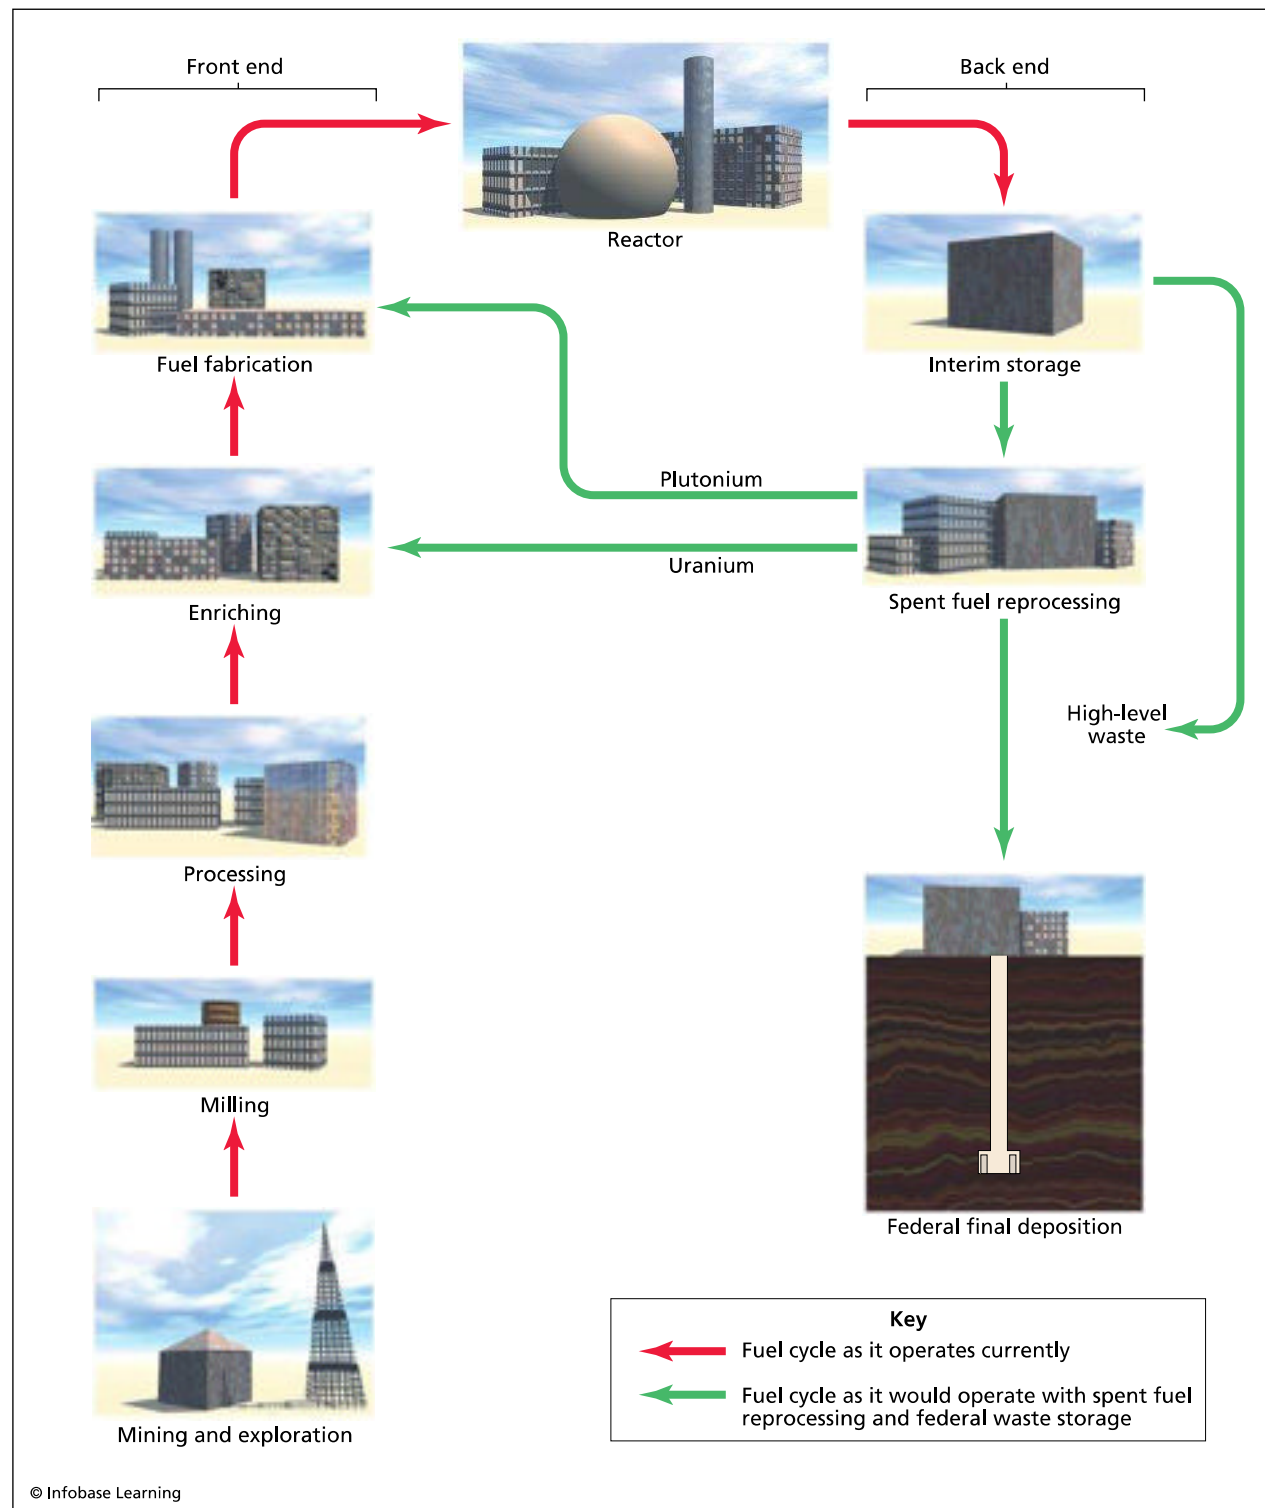

## **SITE CHARACTERISTICS**

Yucca Mountain is composed largely of Miocene age (5–20 million years old) silica-bearing volcanic ash flow and ash fall deposits that have been consolidated and hardened over time into the volcanic rock tuff. The ash that forms the tuff was produced by a series of extensive, and explosive, volcanic eruptions. The rock layer, or “disposal horizon,” where the waste will be placed, the Topopah Springs welded tuff, has physical, chemical, and thermal characteristics that make it a suitable host formation. Given the favorable host rock characteristics, many scientific and engineering studies have focused on water as the most likely way that wastes or waste by-products could escape the repository.

Yucca Mountain is in the southern part of the Great Basin physiographic province, an area that receives

only about six inches (15 cm) of rainfall or less per year. Most of this precipitation quickly evaporates or is absorbed by the area's sparse vegetative cover. The types of infiltration, or "bathtub" effects, where water ponds around the waste, that are common at so many

other disposal sites in more humid climatic zones are very unlikely to occur at Yucca Mountain. In addition, the heat being generated as part of the radioactive decay process will probably quickly evaporate water that does reach the disposal horizon.

Schematic diagram for obtaining, processing, utilizing, recycling, and disposing of nuclear fuel

The regional groundwater table is almost 1,000 feet (305 m) below the disposal horizon, and modeling studies have found that by the time waste or waste by-products are able to move through this thick, dry buffer zone, the radioactive substances would have decayed to greatly reduced levels. The groundwater that is present underneath Yucca Mountain moves very slowly and discharges onto the surface 30–45 miles (50–70 km) to the south of the site and possibly as far away as south-central Death Valley in California. These long travel times allow radioactive decay to reduce the toxicity of materials that may leak from Yucca Mountain and help reduce the risk of exposure. The tuff also contains zeolite, a hydrated, aluminosilicate mineral with a microporous structure that can hold a wide variety of cations. Commonly used as ion-exchange media in commercial water softeners, zeolites attract and retain many types of radioactive ions within their crystal lattice. This property can greatly slow the movement of radioactive ions through the groundwater.

Nevada ranks third in the nation in current seismic activity, and, since 1976, there have been more than 600 seismic events with a magnitude greater than 2.5 within a 50-mile (81-km) radius of Yucca Mountain. The mountain itself was largely formed as a result of earthquake-induced faulting and strong ground motion events that occurred over several million years. Site developers concluded that seismic and related tectonic effects on the natural systems at Yucca Mountain are occurring very slowly. Yucca Mountain has remained geologically stable for at least the last several million years. Faulting and seismic activity should not significantly affect repository performance, especially given the engineered barrier systems that have been implemented at the facility.

### THE CHOICE OF YUCCA MOUNTAIN

The ultimate choice of Yucca Mountain by the Department of Energy (DOE) as the repository was far from certain. In 1981, on the basis of information from the National Academy of Sciences and other well-respected scientific bodies, the U.S. Congress mandated that the U.S. Department of Energy (DOE) identify a geologic or underground repository for the disposal of the nation's high-level radioactive waste. By 1983, nine potential sites in six states had been identified: two salt beds in Texas; two salt beds in Utah; three salt domes, two in Mississippi and one in Louisiana; one site in the basalt of Washington State; and the welded tuff (ignimbrite) of Yucca Mountain in Nevada. After some additional

screening, the DOE recommended the Deaf Smith County Texas salt bed and Yucca Mountain for full characterization. On February 12, 2002, after almost 10 years of study, the DOE announced that Yucca Mountain was the most appropriate place to dispose of these dangerous wastes permanently. As might be expected, the governor of Nevada did not agree and appealed to Congress to void the DOE's decision. Neither Congress nor President George W. Bush would do so.

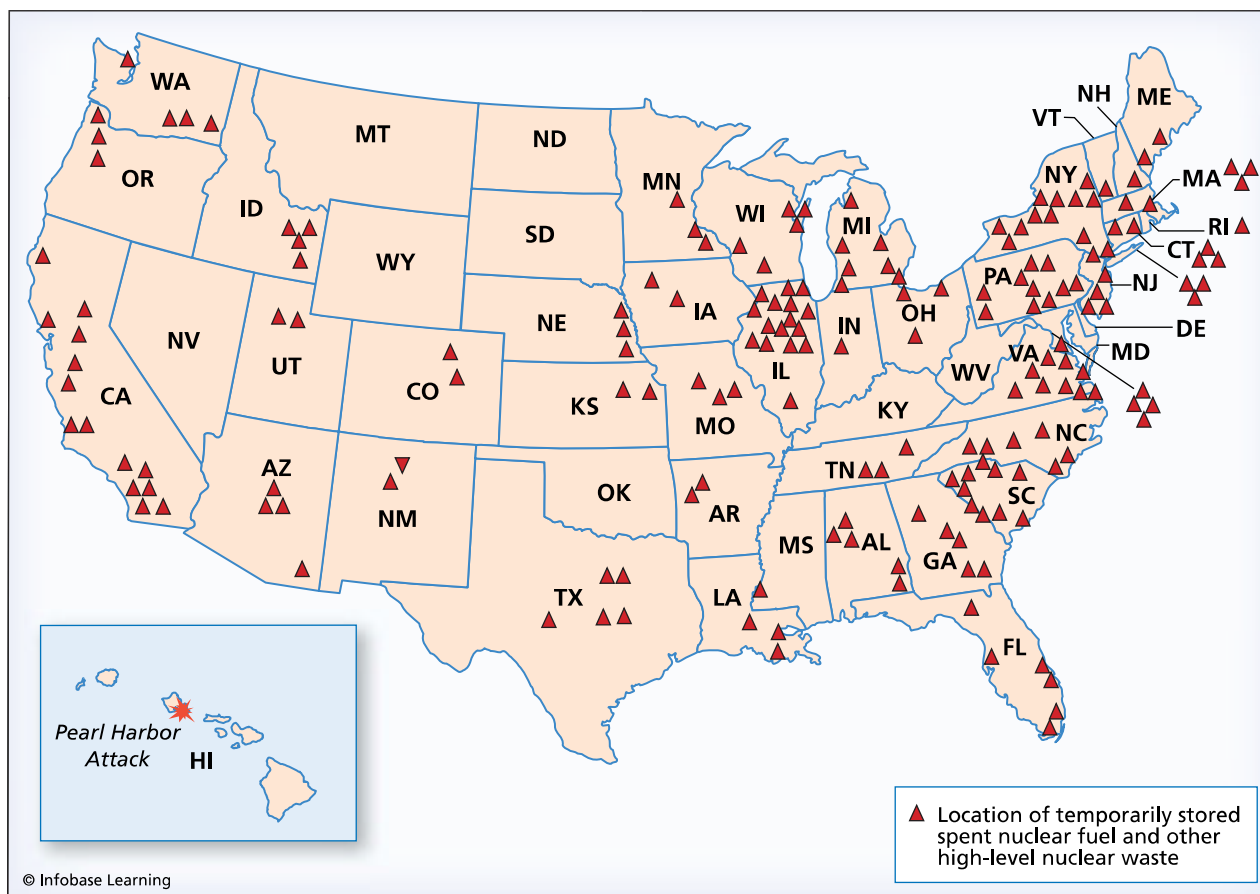

Besides its geologic and climatological setting, Yucca Mountain had a number of other attractive features. It is adjacent to the Nevada Test Site, 1,350 square miles (3,497 km<sup>2</sup>) of U.S. government-owned land used since the late 1940s for the above- and belowground detonation of almost 1,000 nuclear devices. Ellis Air Force Base is close by, along with the notorious "Area 51" of UFO fame. The DOE also counted on public support, as Nevada is more dependent on nuclear energy than many other states, with about 15 percent of Las Vegas's electricity supplied by the Palo Verde nuclear plant. Finally, when Yucca Mountain was nominated as a finalist site in the early 1980s, Nevada had only two congressmen. According to numerous newspaper and public research polls, the majority of Nevadans oppose the development of Yucca Mountain as a geologic repository for nuclear waste.

### PRODUCTION OF THE REPOSITORY

A consortium of government contractors is developing Yucca Mountain, and approximately 1,300 people work on the project. Projecting off the main U-shaped tunnel are large open rooms or vaults, where the majority of the research and testing is performed. Smaller side tunnels to be dug at right angles to the main tunnel will be used for waste disposal. The final repository will be 1,000 feet (305 m) below the ground and cover almost 1,200 acres (486 ha). The disposal horizon also will be 1,000 feet (305 m) above the top of the water table. Multilayer stainless steel and nickel alloy packages will be used to hold the waste, and these will be surrounded by titanium drip and rock shields.

Belowground workings at Yucca Mountain will consist of two inclined access ramps, vertical ventilation shafts, and flat-lying waste emplacement drifts. These drifts will be divided into two sets of waste disposal areas called blocks. The upper block, approximately 800 acres (324 ha), will be able to hold about 11,000 waste packages. The lower block, about 170 acres (69 ha), will accommodate up to 2,400 waste packages. Overall, those facilities cur-

**Map of the United States showing the locations of temporary waste repositories for spent nuclear fuel and other high-level nuclear waste in 1994. They await transport to a permanent site, such as Yucca Mountain in Nevada.**

rently storing high-level wastes around the United States including nuclear power plants, research facilities, and military operations are expected to ship 12,000 specially designed waste packages to Yucca Mountain for disposal.

Finally, the last defense against water is the containers into which the waste materials will be placed for disposal. Each is constructed of two layers, first, a four-inch- (100-mm-) thick outer barrier designed to withstand conditions that will be present after the initial placement of the container in the disposal block, namely, humid air at elevated temperatures. This outer barrier will be made up of a mixture of nickel, chromium, molybdenum, iron, tungsten, and cobalt. Over time, conditions inside the repository may become cooler and wetter and a second, 0.8-inch- (20-mm-) thick corrosion barrier also will be installed inside each disposal container to provide additional protection from those conditions. This layer, a titanium alloy, forms a passive oxide film over its surface that is stable over a wide range of temperature, pH, and moisture conditions. Disposal container lids for both inner and outer layers will

be welded on by using remote procedures that will take up to 33 hours per container. These containers have been designed to remain intact for thousands of years but do not shield or prevent the escape of radioactivity. That is the purpose of the geologic repository.

The total cost of site development is expected to be in the range of \$100 billion, with most of this paid for as a surcharge on electricity produced by nuclear power plants. Of course, this surcharge is passed along to the public in monthly utility bills. The federal government also is paying part of the cost, with money being allocated from taxpayer-funded U.S. Department of Defense (DOD) and DOE budgets. Yucca Mountain is anticipated to begin accepting waste for permanent disposal on March 31, 2017.

### A COLLABORATIVE PROJECT

The DOE is responsible for the siting, development, and operation of Yucca Mountain, but a number of other government agencies have been mandated to

make sure the design and long-term performance are protective of the public health and environment. The U.S. Geologic Survey provides technical support in characterization and design studies. The Nuclear Regulatory Commission (NRC) is responsible for determining whether DOE will receive the necessary licenses to dispose of spent nuclear fuel and high-level radioactive waste in the repository. If the Yucca Mountain site is approved to accept waste, shipments by NRC licensees to the site will have to be made in accordance with NRC and Department of Transportation (DOT) regulations. The U.S. Environmental Protection Agency (EPA) has a major role in the development of safety standards for the site. The EPA's standards address all air, groundwater, and soil environmental pathways and have been developed to be protective of public health for the next million years. The EPA has proposed two dose standards. For the first 10,000 years, a dose limit of 15 millirem per year to the general public living in the area of Yucca Mountain is required. This is the most stringent radiation standard in the United States. Between 10,000 and 1 million years, the EPA requires that the facility not expose the public to a dose greater than 350 millirem per year, which is no higher than natural or background radiation levels for this area of the country.

### THE CONTROVERSY

With so much at risk, opponents of this solution to the high-level waste disposal problem regularly challenge the use of Yucca Mountain as a repository. They maintain that the remote nature of the site is being threatened by the explosive growth in and around the city of Las Vegas, only 100 miles (161 km) to the southeast. Population pressures will increase, and risks related to inadvertent human intrusion will become greater over time, especially over the tens of thousands of years when the waste will remain radioactive.

The large-scale volcanic eruptions that produced Yucca Mountain ended about 12 million years ago, and, about 3 million years ago, a series of smaller, less explosive eruptions and lava flows took place in the area. The last such small eruption occurred about 80,000 years ago. Opponents maintain that these types of geologic events are difficult to predict and, if one occurs, it could result in catastrophic failure of the repository.

The rocks at Yucca Mountain are cracked and broken in places. In some cases, these cracks may extend from the planned storage area to the underlying water table. Some hydrologists think that the joints provide a way for radioactive waste to escape the repository after the waste containers fail several tens of thousands of years from now. In addition,

Diagram showing the repository system for high-level nuclear waste that will be used in Yucca Mountain

although rainfall amounts are low now, climate change in the distant future cannot be predicted and may result in increased levels of precipitation, which could increase infiltration into the repository and raise groundwater table elevations.

In March 2005, an investigation by both the DOE and the Department of the Interior found that several U.S. Geological Survey (USGS) hydrologists had exchanged e-mails discussing possible falsification of quality assurance documents on water infiltration research. A subsequent study confirmed the technical soundness of the USGS's infiltration modeling work, but the controversy exemplified the high degree of suspicion and mistrust with which the DOE and its contractors are viewed, especially by Nevadans. To help allay those fears, the DOE has asked that a non-profit consortium of colleges and universities provide independent expert reviews of scientific and technical work being done on Yucca Mountain.

It seemed unlikely, given the time and money spent so far, as well as the growing need for such a facility, that Yucca Mountain would not become the U.S. high-level waste repository. The site had withstood the scientific, technical, legal, and political challenges its opponents have mounted against its use. In 2010, however, President Barack Obama fulfilled one of his campaign promises and directed the DOE to withdraw Yucca Mountain from consideration as a high-level waste disposal site. Numerous lawsuits challenging the legality of the application

withdrawal, because the site was designed by an act of Congress as the nation's high-level waste repository, are currently under way.

# Z

**zinc** Touted as a miracle cure for colds and other health problems, zinc is probably the ultimate substance to contradict the old saying that if a little is good, a lot is better. Like many of the other heavy metals, in trace quantities, zinc is an essential nutrient and an effective health treatment. Zinc is found in virtually all multivitamin supplements. As zinc oxide, it is an effective treatment for skin problems from diaper rash to acne. It is used for prostate health, hair health, and even vision. Zinc is used in its metallic form or mixed with other metals as alloys or in numerous zinc compounds, primarily zinc oxide but also zinc chloride and other zinc salts, zinc sulfide, zinc sulfate, zinc acetate, zinc carbonate, zinc methyl or diethyl, and zinc pyri-thione, among others. On the other hand, in high concentrations, it is an environmental and human health threat. It is found in so many substances—from galvanized metal to paint to coins—that exposure is a foregone conclusion, making it even more dangerous. Zinc and zinc compounds have been identified in 985 of the first 1,662 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List), among the highest percentages of any environmental contaminant. For this reason, zinc was ranked the 74th most dangerous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

## PROPERTIES, USE, AND PRODUCTION

Zinc is a naturally occurring inorganic element or pollutant that can be found in most rocks and soils throughout the world in various concentrations. The most common mineral form is sphalerite, which is

a zinc sulfide. The use of zinc by humans began by at least 1000 B.C.E., when it was used both as a component of brass and as a medicine. It was first recognized as a separate metal by 1374 in India as the eighth metal known at that time. The first zinc smelter was constructed in 1743, and hot galvanizing as corrosion prevention was invented in 1836. The first zinc production in the United States began in 1850.

In 2007, mine production in the United States was 815,000 tons (740,000 metric tons), having generally decreased from 858,000 tons (780,000 metric tons) in 2002. Imports in 2007 totaled 418,000 tons (380,000 metric tons) of ore and 759,000 tons (693,000 metric tons) of refined zinc, which is about average for the past five years (average 784,400 metric tons). Domestic production was from mines in Alaska, Missouri, Montana, and Washington. Imports of ore are mainly from Peru (62 percent), Australia (18 percent), Ireland (11 percent), and Mexico (8 percent); refined metal is from Canada (63 percent), Mexico (18 percent), and Kazakhstan and Brazil (4 percent each). In 2007, some 462,000 tons (420,000 metric tons) was from waste and scrap, 85 percent of which was from Canada.

In 2006, domestic consumption of zinc was used 55 percent in galvanizing, 21 percent in zinc-based alloys, and 16 percent in brass and bronze, primarily in the metals industry. Zinc compounds were used in agriculture, the chemical industry, paint, and the rubber industry. Zinc is also used in die casting, linoleum, fireworks, glass and ceramics, batteries, fuel cells, coins, wood preservative, and ointments, among other uses.

## ENVIRONMENTAL RELEASE AND FATE

Zinc is released to the environment through numerous point sources and nonpoint sources. It occurs naturally in rocks and soils and is released during volcanic eruptions, which make it ubiquitous in the environment. High-volume anthropogenic zinc releases are primarily from mining and refining, steel and alloy production, coal-fired power plants, and waste incineration, but low-level release is widespread. The industrial releases are primarily to the air in the form of fine dust that may or may not attach to particulate and settle to the ground and surface water or be washed out by precipitation. Zinc is naturally present in soils; high concentrations may result from industrial dumping, but also from residential and municipal sources in the form of solid waste, sludge, and fertilizer. Most zinc attaches to soil particles and remains fixed. Some zinc compounds, however, dissolve under certain conditions, including low pH, and leach into the groundwater system. Most particulate zinc in surface water settles to the bottom and remains fixed in the sediments. Zinc can bioaccumulate in fish.

Annual industrial release of zinc to the environment in the United States is enormous. According to the EPA Toxics Release Inventory (TRI) for 2006, there was a total industrial release of 794,261,212 pounds (361,027,823 kg) for all zinc compounds and 79,379,490 pounds (36,081,586 kg) for zinc fumes or dust.

## HEALTH EFFECTS FROM EXPOSURE

Even though small amounts of zinc are vital to survival, higher amounts can cause myriad adverse health effects, as can certain forms at low amounts. Inhalation exposure to zinc fumes from welding, smelting, and other metallurgy on an acute basis can cause a short-term disease called metal fume fever with zinc shakes or chills. This condition is characterized by flulike symptoms including headache, fever, chills, muscle aches, irritation of the nasal passage, cough, reduced lung capacity, nausea, vomiting, fatigue, gastrointestinal distress, weakness, and tiredness. Inhalation of zinc chloride causes nose and throat irritation, cough, chest pain, pulmonary inflammation and pulmonary fibrosis, headache, nausea, and vomiting. Oral ingestion of high doses of zinc causes nausea, vomiting, diarrhea, and abdominal and possible gastric bleeding. Zinc chloride ingestion causes mouth and throat pain, pharyngitis, esophagitis, and pancreas damage. Zinc phosphide reacts with stomach acid to produce phosphine gas, which causes vomiting, abdominal cramping, leth-

argy, hypotension, cardiac arrhythmia, circulatory collapse, pulmonary edema, convulsions, kidney damage, coma, and death within two weeks. Long-term chronic exposure primarily causes anemia and damage to the pancreas and possibly the kidneys and liver. Laboratory animals also had skin irritation and fertility problems in addition to the problems observed in humans. Zinc is classified in EPA group D, not classified with regard to its potential as a carcinogen. Some studies suggest an increase in lung cancer, lymphoma, and tumors in general in laboratory animals, but none is considered definitive.

## REGULATIONS ON HUMAN EXPOSURE

As a result of its widespread distribution and the potential adverse health effects, zinc exposure is regulated by several federal agencies, but the regulations are probably the least stringent for all of the heavy metals. The EPA limits zinc in drinking water to 5 milligrams per liter or less largely because it affects the taste. They also require the reporting of spills to the National Response Center, but the minimal amount is a large 1,000 pounds (454.5 kg) for the most dangerous of zinc and zinc compounds (zinc phosphide, for example) and 5,000 pounds (2,273 kg) for the rest. The Occupational Safety and Health Administration (OSHA) set a limit of 1 milligram of zinc chloride per cubic meter of workplace air and 5 milligrams of zinc oxide per cubic meter of workplace air for an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) sets a limit of 1 milligram of zinc oxide per cubic meter of workplace air for a 10-hour day, 40-hour workweek. The NIOSH National Occupational Exposure Survey of 1981–83 found that many American workers were exposed to many forms of zinc. Some of the exposure levels include 492,366 workers for zinc oxide, 89,451 for zinc sulfate, 79,920 for zinc dust, 56,944 for zinc sulfide, and 26,421 for zinc phosphate.

# APPENDIX I

## LIST OF ACRONYMS

### A

**AA (Atomic Absorption)** a laboratory analytical method commonly used for the detection of metals in soil and groundwater

**AAI (all appropriate inquiry)** due diligence process used to establish “innocent owner” protection status under CERCLA

**AANWR (Alaskan Arctic National Wildlife Refuge)** a protected area possibly containing large amounts of untapped petroleum reserves

**ABEL** the EPA’s computer model for analyzing a violator’s ability to pay a civil penalty

**ACBM** Asbestos-Containing Building Material

**ACFM** Actual Cubic Feet per Minute, a measure of gaseous discharge

**ACGIH** American Conference of Governmental Industrial Hygienists

**ACL (Alternate Concentration Limit)** a risk-based, higher numerical value often proposed by a responsible party as a substitute for a lower (more strict) soil or groundwater cleanup standard

**ACM** Asbestos-Containing Material

**ACO (Administrative Consent Order)** a USEPA and state legal enforcement tool

**ACOE** Army Corps of Engineers

**ACWM** Asbestos-Containing Waste Material

**ADD (Average Daily Dose)** used in risk assessment to calculate safe exposure levels

**ADI (Acceptable Daily Intake)** used in risk assessment to determine acceptable levels of exposure

**AEA** Atomic Energy Act

**AFCEE** Air Force Center for Environmental Excellence

**AGST** Above Ground Storage Tank

**AHERA** Asbestos Hazard Emergency Response Act

**AHM** Acutely Hazardous Material, as defined in RCRA

**AHU** Air Handling Unit

**AI** Active Ingredient

**AL** Acceptable Level

**ALARA** As Low as Reasonably Achievable, a performance based standard related to radiation exposure

**AMSL** Above Mean Sea Level

**AOC** Area of Concern, a location on a site requiring investigation to confirm whether a release of hazardous wastes or substances may have occurred

**APCD** Air Pollution Control District (California)

**API** American Petroleum Institute

**AQI** Air Quality Index

**AQMP** Air-Quality Management Plan

**AR** Administrative Record

**ARAR** Applicable or Relevant and Appropriate Standards, Limitations, Criteria, and Requirements, part of the CERCLA process that defines cleanup standards for a particular Superfund site

**ARCS** Alternative Remedial Contract Strategy, contracting vehicle used by USEPA to authorize Superfund site cleanups

**ASHAA** Asbestos in Schools Hazard Abatement Act

**AST** Aboveground Storage Tank

**ASTHO** Association of State and Territorial Health Officers

**ASTM** American Society for Testing and Materials

**ASTSWMO** Association of State and Territorial Solid Waste Management Officials

**ATCM** Air Toxic Control Measure

**ATSDR** Agency for Toxic Substances and Disease Registry

**AWRA** American Water Resources Association

**AWWA** American Water Works Association

### B

**BACM** Best Available Control Measures, a technology standard required under CWA, CAA, or other federal regulations

- BACT** Best Available Control Technology, a technology standard required under CWA, CAA, or other federal regulations
- BADT** Best Available Demonstrated Technology, a technology standard required under CWA, CAA, or other federal regulations
- BAF** Bioaccumulation Factor, the rate that a contaminant will be incorporated into an organism
- BART** Best Available Retrofit Technology, a technology standard required under CWA, CAA, or other federal regulations
- BAT** Best Available Technology, a technology standard required under CWA, CAA, and/or federal regulations
- BATEA** Best Available Treatment Economically Achievable, a technology standard required under CWA, CAA, or other federal regulations
- BCPCT** Best Conventional Pollutant Control Technology, a technology standard required under CWA, CAA, or other federal regulations
- BCT** Best Control Technology, a technology standard required under CWA, CAA, or other federal regulations
- BDAT** Best Demonstrated Achievable Technology, a technology standard required under CWA, CAA, or other federal regulations
- BDCT** Best Demonstrated Control Technology, a technology standard required under CWA, CAA, or other federal regulations
- BDT** Best Demonstrated Technology, a technology standard required under CWA, CAA, or other federal regulations
- BGL** Below Ground Level
- BGS** Below Ground Surface
- BIF** Boiler and Industrial Furnace
- BIOPLUME** Computer model used to predict the extent of groundwater contamination
- BMP** Best Management Practice(s), a technology standard required under CWA, CAA, and other federal regulations
- BNA** Bureau of National Affairs, an environmental database company
- BOD** Biochemical Oxygen Demand or Biological Oxygen Demand, a measure of water quality
- BPT** Best Practicable Technology, a technology standard required under CWA, CAA, or other federal regulations
- BPWTT** Best Practical Wastewater Treatment Technology, a technology standard required under CWA, CAA, or other federal regulations
- BRAC** Base Realignment and Closure
- BTEX** Benzene, Toluene, Ethylbenzene, Xylene, the principal components of gasoline
- C**
- CAA** Clean Air Act
- CAAA** Clean Air Act Amendments
- CAER** Community Awareness and Emergency Response
- CAIR** Clean Air Interstate Rule
- CAM** Compliance Assurance Monitoring rule
- CAMP** Continuous Air Monitoring Program
- CAMR** Clean Air Mercury Rule
- CAMU** Corrective Action Measures Unit, a specially designed disposal area for wastes generated during the cleanup of an RCRA-regulated site
- CAO** Corrective Action Order, as defined in RCRA
- CAP** Corrective Action Plan
- CAR** Corrective Action Report
- CAS** Chemical Abstract Service
- CBI** Confidential Business Information, as defined in TSCA and other federal regulations
- CCAA** Canadian Clean Air Act
- CCTP** Clean Coal Technology Program
- CDI** Chronic Daily Intake
- CE** Categorical Exclusion, a type of federal action that does not require an EIS under NEPA
- CEC** Cation Exchange Capacity, a measure of a soil's ability to retain positively charged ions (metals). Often used as an indicator of a soil's ability to protect groundwater from contamination
- CEM** Continuous Emission Monitoring, required under the CAA for facilities that violate permit limitations
- CEMS** Continuous Emission Monitoring System
- CEQ** Council on Environmental Quality
- CERCLA** Comprehensive Environmental Response, Compensation, and Liability Act
- CERCLIS** Comprehensive Environmental Response, Compensation, and Liability Information System
- CESQG** Conditionally Exempt Small Quantity Generator, as defined in RCRA
- CFC** Chlorofluorocarbons, chemicals that interfere with the production of ozone in the upper atmosphere
- CFM** Chlorofluoromethanes, chemicals that interfere with the production of ozone in the upper atmosphere
- CFR** Code of federal regulations
- CFS** Cubic Feet per Second
- CGL** Comprehensive General Liability, a type of insurance coverage
- CHP** Certified Health Professional

**CIH** Certified Industrial Hygienist  
**CLP** Contract Laboratory Program  
**CM** Corrective Measure, a cleanup action required under RCRA  
**CMI** Corrective Measures Implementation, a RCRA-regulated cleanup program  
**CMS** Corrective Measure Study, a site investigation performed under RCRA  
**CNG** Compressed Natural Gas  
**CO** Consent Order, a legal enforcement tool used by EPA and the states to force compliance with environmental regulations  
**COC** Chemical of Concern, a possible contaminant in soil or groundwater  
**COD** Chemical Oxygen Demand, a measure of water quality  
**COH** Coefficient of Haze, an indicator of air quality  
**CPF** Carcinogenic Potency Factor, a term used in risk assessments  
**CPOEC** Contaminant of Potential Ecological Concern  
**CSO** Combined Sewer Overflow, when storm water and sanitary wastewater are carried in the same collection system and discharge into the environment without treatment  
**CSP** Certified Safety Professional  
**CWA** Clean Water Act (a.k.a. FWPCA)  
**CWAP** Clean Water Action Project, usually an upgrade to an existing sewage treatment plant funded through the CWA grant program  
**CZMA** Coastal Zone Management Act  
**CZMARA** Coastal Zone Management Act Reauthorization Amendments

## D

**DAF** Dilution Attenuation Factor, a measure of how site-specific conditions may dilute a contaminant once it has been released into the environment  
**DBP** Disinfection By-Product, a group of chemicals regulated under the Safe Drinking Water Act  
**DEC** Department of Environmental Conservation, a state agency responsible for development and enforcement of environmental regulations  
**DEP** Department of Environmental Protection, a state agency responsible for development and enforcement of environmental regulations  
**DEQ** Department of Environmental Quality, a state agency responsible for development and enforcement of environmental regulations  
**DL** Detection Limit, the lowest level that a laboratory method can reliably “see” or detect a contaminant  
**DMR** Discharge Monitoring Report, a regular listing (monthly, quarterly, etc.) of contaminants released into the surface water by a facility with a NPDES permit  
**DNA** Deoxyribonucleic acid  
**DNAPL** Dense Nonaqueous Phase Liquid, a contaminant that forms a layer near the bottom of the water table  
**DO** Dissolved Oxygen, a measure of water quality  
**DOD** Department of Defense  
**DOE** Department of Energy  
**DOI** Department of Interior  
**DOJ** Department of Justice  
**DOT** Department of Transportation  
**DPT** Direct Push Technology, a method used to drill shallow soil borings by using a vibrating hammer to drive or “push” a hollow steel sampling tube into the ground  
**DQO** Data Quality Objectives  
**DRE** Destruction and Removal Efficiency, a performance standard established in the CAA  
**DRO** Diesel Range Organics, a class of contaminants originating from a release of heavier, less refined petroleum products (diesel fuel or heating oil)  
**DSCF** Dry Standard Cubic Feet, a measure of gaseous discharge  
**DSCM** Dry Standard Cubic Meter  
**DTB** Depth To Bottom, usually used to signify the depth to which a boring or monitor well has been drilled  
**DTP** Depth to Product, the distance from the top of a monitoring well or boring to the depth below grade at which a separate phase contaminant (e.g., floating oil) is present in the groundwater  
**DTW** Depth to Water, the distance from the top of a boring or monitoring well to the top of the water table  
**DWS** Drinking Water Standard, as defined in the CWA

## E

**EA** Endangerment Assessment, as described in CERCLA  
**EA** Environmental Assessment, as described in NEPA  
**EA** Environmental Audit  
**EAF** Electric Arc Furnaces  
**EAO** Emergency Administrative Order  
**EAP** Environmental Action Plan  
**EC** Effective Concentration, used in risk assessment to calculate potential exposure rates

- ED** Effective Dose
- EDD** Enforcement Decision Document, the basis for a regulatory action (ACO)
- EDF** Environmental Defense Fund
- EDRS** Enforcement Document Retrieval System
- EDTA** Ethylenediaminetetraacetic Acid
- EER** Excess Emission Reports
- EF** Emission Factor, as defined in CAA
- EGR** Exhaust Gas Recirculation, a type of air pollution control technology
- Eh** Redox Potential, a measure of water's oxidizing capacity
- EHS** Extremely Hazardous Substance, as defined in RCRA
- EI** Emissions Inventory, as defined in CAAA
- EIA** Environmental Impact Assessment, as defined in NEPA
- EIL** Environmental Impairment Liability, a type of insurance policy
- EIR** Environmental Impact Report
- EIS** Environmental Impact Statement, as defined in NEPA
- EJ** Environmental Justice
- EL** Exposure Level
- ELI** Environmental Law Institute
- ELR** Environmental Law Reporter
- EM** Electromagnetic Conductivity, a technique used to detect buried metal objects
- EMR** Environmental Management Report
- EMS** Enforcement Management System
- EMSL** Environmental Monitoring Support Systems Laboratory
- EO** Ethylene Oxide
- EOB** End of Boring, the depth below grade at which subsurface drilling ceased
- EOP** End of Pipe, a discharge point defined by the CWA
- EOT** Emergency Operations Team
- EPA** Environmental Protection Agency, branch of federal government responsible for developing and enforcing environmental laws and policies
- EPACT** Environmental Policy Act
- EPA ID #** Identifier assigned to a generator of hazardous waste by USEPA
- EPC** Exposure Point Concentration, a risk assessment uptake parameter
- EPCRA** Emergency Planning and Community Right to Know Act (SARA)
- EPI** Environmental Policy Institute
- EPRI** Electric Power Research Institute
- EPTC** Extraction Procedure Toxicity Characteristic
- ERC** Environmental Research Center, also Emissions Reduction Credit, as defined in CAA
- ERCS** Emergency Response Cleanup Services, a contracting vehicle used by USEPA to investigate and remediate Superfund sites
- ERL** Environmental Research Laboratory
- ERNS** Emergency Response Notification System
- ERT** Emergency Response Team
- ES** Enforcement Strategy
- ESA** Endangered Species Act; also Environmental Site Assessment, as defined in CERCLA
- ESCA** Electron Spectroscopy for Chemical Analysis, a laboratory analytical method
- ES&H** Environmental Safety and Health, a general term used by many companies to describe the functional part of their organization responsible for environmental and safety compliance
- ESP** Electrostatic Precipitators, an air pollution control device
- ET** Emissions Trading, as defined in CAAA
- ETP** Emissions Trading Policy, as defined in CAAA
- ETS** Emissions Tracking System
- F**
- FBC** Fluidized Bed Combustion, a type of incinerator
- FCAA** Federal Clean Air Act
- FCC** Fluid Catalytic Converter, an air treatment technology
- FDA** Food and Drug Administration
- FDf** Fundamentally Different Factors, as defined in the CWA
- FE** Fugitive Emissions, as defined in the CAA
- FEMA** Federal Emergency Management Agency
- FEPCA** Federal Environmental Pesticide Control Act; enacted as amendments to FIFRA
- FERC** Federal Energy Regulatory Commission
- FFDCA** Federal Food, Drug, and Cosmetic Act
- FGD** Flue-Gas Desulfurization, a type of air pollution treatment technology
- FID** Flame Ionization Detector, a laboratory instrument
- FIFRA** Federal Insecticide, Fungicide, and Rodenticide Act
- FIM** Friable Insulation Material, a type of ACM
- FIP** Final Implementation Plan, as defined in CAA
- FLP** Flash Point
- FLPMA** Federal Land Policy and Management Act
- FML** Flexible Membrane Liner, used in landfills to control leachate migration
- FOIA** Freedom of Information Act
- FONSI** Finding of No Significant Impact, as defined in NEPA
- FP** Fine Particulate, a type of air pollutant
- FPA** Federal Pesticide Act

**FPD** Flame Photometric Detector, a laboratory instrument

**FPPA** Federal Pollution Prevention Act

**FQPA** Food Quality Protection Act

**FR** Federal Register

**FS** Feasibility Study, as defined in CERCLA

**FSA** Food Security Act

**FSP** Field Sampling Plan, methodologies to collect representative samples of soil, groundwater, and other types of media

**FTP** Federal Test Procedure for motor vehicle emissions

**FWCA** Fish and Wildlife Coordination Act

**FWPCA** Federal Water Pollution and Control Act (a.k.a. CWA)

**FY** Fiscal Year

## G

**GAC** Granular Activated Carbon, used in treatment of contaminated water and air

**GACT** Granular Activated Carbon Treatment

**GC** Gas Chromatograph, may be dual-flame or electron capture

**GC/MS** Gas Chromatograph/Mass Spectrograph, a laboratory analytical instrument

**GEP** Good Engineering Practice, a management standard defined in CWA, CAA, and other federal regulations

**GIS** Geographic Information Systems

**GLC** Gas Liquid Chromatography, a laboratory analytical instrument; also Ground Level Concentration, a term used in risk assessment

**GLERL** Great Lakes Environmental Research Laboratory

**GLP** Good Laboratory Practices, a management standard for the operation of an analytical laboratory

**GOCO** Government-Owned/Contractor-Operated, a contracting system for the operation of federal facilities

**GOGO** Government-Owned/Government-Operated

**GOPO** Government-Owned/Private-Operated

**GPAD** Gallons per acre per day

**GPM** Gallons per Minute, a measure of discharge

**GPR** Ground-Penetrating Radar

**GPS** Global Positioning System, satellite location system

**GRO** Gasoline Range Organics, types of constituents found in soil and groundwater as a result of a release of gasoline into the environment

**GWDR** Ground Water Disinfection Rule, as defined in the CWA

**GWM** Groundwater Monitoring

**GWP** Global Warming Potential

**GWPS** Groundwater Protection Standard, as defined in the CWA

## H

**HA** Health Advisory, as defined in the SDWA

**HAP** Hazardous Air Pollutant, as defined in the CAA

**HAZMAT** Hazardous Materials, as defined in RCRA and CERCLA

**HAZOP** Hazard and Operability Study

**HBFC** Hydrobromofluorocarbon, an ozone depleting substance

**HC** Hazardous Constituents; also Hydrocarbon

**HCCPD** Hexachlorocyclopentadiene

**HCFC** Hydrochlorofluorocarbon, an ozone depleting substance

**HCS** Hazard Communication Standard, as defined by OSHA

**HDPE** High-Density Polyethylene

**HDT** Highest Dose Tested, in a study

**HEAL** Human Exposure Assessment Location, a term used in risk assessment

**HEPA** High-Efficiency Particulate Air, a type of air pollution control device

**HFC** Hydrofluorocarbon

**HHE** Human Health and the Environment, a general term used to describe protectiveness of an environmentally related action

**HHRA** Human Health Risk Assessment

**HHV** Higher Heating Value

**HHW** Household Hazardous Waste

**HI** Hazard Index, a term used in risk assessment

**HLRW** High-Level Radioactive Waste

**HMIS** Hazardous Materials Information System

**HMRT** Hazardous Materials Response Team

**HMS** Hazardous Materials Storage

**HMTA** Hazardous Materials Transportation Act

**HMTC** Hazardous Materials Technology Center, part of DOT

**HMTR** Hazardous Materials Transportation Regulations

**HOC** Halogenated Organic Carbons

**HON** Hazardous Organic NESHAP, as defined in the CAA

**HOV** High-Occupancy Vehicle

**HP** Horsepower

**HPLC** High-Performance Liquid Chromatography, a laboratory analytical procedure

**HPV** High-Priority Violator, a term used in federal legal enforcement actions

**HRA** Health Risk Assessment

**HRS** Hazardous Ranking System or Score, as defined in CERCLA

**HS** Hazardous Substance  
**HSL** Hazardous Substance List, as defined in CERCLA and RCRA  
**HSWA** Hazardous and Solid Waste Amendments, as related to RCRA  
**HVAC** Heating, Ventilation, and Air-Conditioning system  
**HW** Hazardous Waste  
**HWIR** Hazardous Waste Identification Rule, as defined in RCRA  
**HWLT** Hazardous Waste Land Treatment, as defined in RCRA  
**HWM** Hazardous Waste Management, a general term used to describe overall procedures for the control of a company's or facility's waste streams  
**HWMU** Hazardous Waste Management Unit, as defined by RCRA

## I

**IA** Interagency Agreement, an agreement between federal agencies to perform an action  
**IAP** Indoor Air Pollution  
**IAQ** Indoor Air Quality  
**IARC** International Agency for Research on Cancer  
**ICAP** Inductively Coupled Argon Plasma, a laboratory analytical instrument  
**ICBN** International Commission on the Biological Effects of Noise  
**ICCP** International Climate Change Partnership  
**ICP** Inductively Coupled Plasma, a laboratory analytical instrument for inorganic materials  
**ICP-MS** Inductively Coupled Plasma—Mass Spectrometer, for inorganic trace elements  
**ICR** Information Collection Rule, as defined in SDWA  
**ICRE** Ignitability, Corrosivity, Reactivity, Extraction, as described in RCRA  
**ICRP** International Commission on Radiological Protection  
**ICWM** Institute for Chemical Waste Management  
**IDLH** Immediately Dangerous to Life and Health  
**IDW** Investigation Derived Waste, material generated during a site investigation (e.g., drill cutting or used protective clothing)  
**IEB** International Environment Bureau  
**IES** Institute for Environmental Studies  
**IFB** Invitation for Bid, part of the federal procurement process  
**IFCS** International Forum on Chemical Safety  
**IGCI** Industrial Gas Cleaning Institute  
**IJC** International Joint Commission (on Great Lakes)  
**I/M** Inspection/Maintenance  
**IMS** Ion Mobility Spectrometry, a laboratory analytical procedure  
**IOB** Iron Ore Beneficiation, process used to increase iron concentration of an ore  
**IOU** Input/Output Unit  
**IP** Inhalable Particle, a type of air pollution  
**IPCC** Intergovernmental Panel on Climate Change  
**IPCC** Intergovernmental Panel on Climate Control  
**IPCS** International Program on Chemical Safety  
**IPM** Integrated Pest Management  
**IRA** Interim Removal Action, as defined in CERCLA  
**IRIS** Integrated Risk Information System, a catalog of chemical health effects used by EPA in risk assessments  
**IRM** Intermediate Remedial Measures, as defined in CERCLA  
**IRP** Installation Restoration Program for military bases  
**IRPTC** International Register of Potentially Toxic Chemicals  
**IRR** Institute of Resource Recovery  
**IS** Interim Status for a TSDF, as defined in RCRA  
**ISE** Ion-Specific Electrode, a type of analytical instrument for elemental concentrations  
**ISO** International Organization for Standardization  
**ISV** In Situ Vitrification, a process to treat soil containing hazardous wastes  
**ITC** Innovative Technology Council  
**ITC** Interagency Testing Committee  
**ITRC** Interstate Technology Regulatory Coordination  
**IWS** Ionizing Wet Scrubber, a type of air pollution control device

## J

**JECFA** Joint Expert Committee of Food Additives  
**JEIOG** Joint Emissions Inventory Oversight Group  
**JLC** Justification for Limited Competition, part of the federal procurement process  
**JNCP** Justification for Non-Competitive Procurement, part of the federal procurement process  
**JOFOC** Justification for Other than Full and Open Competition, part of the federal procurement process  
**JPA** Joint Permitting Agreement, between federal agencies  
**JTU** Jackson Turbidity Unit, a measure of water quality

## L

**LADD** Lifetime Average Daily Dose; Lowest Acceptable Daily Dose, terms used in risk assessment

- LAER** Lowest Achievable Emission Rate, as defined in CAA
- LBP** Lead-Based Paint
- LC** Lethal Concentration, a term used in risk assessment
- LC** Liquid Chromatography, a laboratory analytical instrument
- LCD** Local Climatological Data
- LCRS** Leachate Collection and Removal System
- LD** Land Disposal
- LD10** Lethal Dose 10 percent, the lowest dosage of a toxic substance that kills test organisms
- LD50** Lethal Dose 50 percent, the dose at which 50 percent of the test subjects die
- LDAR** Leak Detection and Repair, used for underground storage tank systems
- LDC** London Dumping Convention in ocean waters
- LDCRS** Leachate Detection, Collection, and Removal System
- LDR** Land Disposal Restrictions, as defined in RCRA
- LDS** Leak Detection System, for underground storage tank systems
- LEA** Local Enforcement Agency
- LEL** Lowest Effect Level, a term used in risk assessment
- LEL** Lower Explosive Limit for gaseous contaminants
- LEPC** Local Emergency Planning Committee, as defined in SARA
- LERC** Local Emergency Response Committee, as defined in SARA
- LEV** Low Emissions Vehicle, as defined in CAA
- LFG** Landfill Gas
- LFL** Lower Flammability Limit for gaseous contaminants
- LIMB** Limestone-Injection Multistage Burner, a type of incinerator
- LLRW** Low-Level Radioactive Waste
- LMFBR** Liquid Metal Fast Breeder Reactor
- LNAPL** Light Nonaqueous Phase Liquid, a type of contaminant that floats on top of the water table
- LOAEL** Lowest Observed Adverse Effect Level, a term used in risk assessment
- LQG** Large Quantity Generator, as defined in RCRA
- LUFT** Leaking Underground Fuel Tank
- LULU** Locally Unwanted Land Use, a land use that may be beneficial for the region (e.g., prison) but is not wanted by those living near it
- LUST** Leaking Underground Storage Tank
- M**
- MAC** Mobile Air Conditioner
- MACT** Maximum Achievable Control Technology, as defined in CAA
- MAER** Maximum Allowable Emission Rate, as defined in CAA
- MARPOL** International Convention for the Prevention of Pollution from Ships
- MATC** Maximum Acceptable Toxic Concentration, a term used in risk assessment
- MBAS** Methylene-Blue-Active Substances, a type of water pollutant
- mcg/L** micrograms per liter, a measure of concentration
- MCL** Maximum Contaminant Level, as defined in SDWA
- MCLG** Maximum Contaminant Level Goal, as defined in SDWA
- mcg/m<sup>3</sup>** micrograms per cubic meter, a measure of contamination in air
- MCS** Multiple Chemical Sensitivity, a term used in risk assessment
- MDL** Method Detection Limit, the lowest contaminant concentration that an analytical method can reliably detect or “see” in a sample
- MEI** Maximally (or Most) Exposed Individual, a term used in risk assessment
- MEP** Multiple Extraction Procedure, a laboratory analytical procedure
- MGD** Millions of Gallons per Day, a measure of discharge
- mg/kg** milligrams per kilogram or ppm, a measure of concentration in solids
- mg/L** milligrams per liter or ppm, a measure of concentration in liquids
- mg/m<sup>3</sup>** milligrams per cubic meter, a measure of concentration in gases
- MGP** Manufactured Gas Plant
- MNA** Monitored Natural Attenuation, a nonactive approach to groundwater remediation
- MOE** Margin of Exposure, a term used in risk assessment
- MOS** Margin of Safety, a term used in risk assessment
- MOU** Memorandum of Understanding, agreement between two governmental agencies or a governmental agency and private party perform some action
- MP** Melting Point
- MPI** Maximum Permitted Intake, a term used in risk assessment
- MPN** Maximum Possible Number, a term used in microbiological analysis
- MPRSA** Marine Protection, Research and Sanctuaries Act
- MRBMA** Mercury-Containing and Rechargeable Battery Management Act

**MRF** Materials Recovery Facility, a type of recycling center  
**MRL** Maximum-Residue Limit, a measure of pesticide tolerance  
**MS** Mass Spectrometer  
**MSDS** Material Safety Data Sheet, as defined by OSHA  
**MSW** Municipal Solid Waste  
**MTD** Maximum Tolerated Dose, a term used in risk assessment  
**MW** Monitoring Well

## N

**NAA** Nonattainment Area, as defined in CAA  
**NAAQS** National Ambient Air Quality Standards, as defined in CAA  
**NAMS** National Air Monitoring Stations  
**NAPAP** National Acid Precipitation Assessment Program  
**NAPL** Nonaqueous Phase Liquid, a separate layer of contaminant that either sinks or floats within the water table  
**NAS** National Academy of Sciences  
**NASA** National Aeronautics and Space Administration  
**NASDA** National Association of State Departments of Agriculture  
**NCAMP** National Coalition against the Misuse of Pesticides  
**NCP** National Contingency Plan, procedures to be used for the investigation and cleanup of CERCLA designated sites  
**NCWS** Non-Community Water System, as defined in SDWA  
**ND** Not Detected; lowest concentration of a contaminant that can be reliably detected or seen by a laboratory's analytical instrument  
**NEPA** National Environmental Policy Act  
**NEPI** National Environmental Policy Institute  
**NESHAP** National Emission Standard for Hazardous Air Pollutants  
**NETA** National Environmental Training Association  
**NFA** No Further Action, a regulatory determination that site investigation or cleanup goals have been achieved  
**NFRAP** No Further Remedial Action Planned, the end of cleanup activities at a site  
**NIEHS** National Institute for Environmental Health Sciences  
**NIOSH** National Institute of Occupational Safety and Health  
**NIPDWR** National Interim Primary Drinking Water Regulations, as defined in SDWA  
**NOAA** National Oceanographic and Atmospheric Agency  
**NOAEL** No Observable Adverse Effect Level, a term used in risk assessment  
**NOEL** No Observable Effect Level, a term used in risk assessment  
**NOV** Notice of Violation, used to notify a facility that a violation of an environmental regulation has occurred  
**NORM** Naturally Occurring Radioactive Material  
**NPDES** National Pollutant Discharge Elimination System, as defined in CWA  
**NPHAP** National Pesticide Hazard Assessment Program  
**NPIRS** National Pesticide Information Retrieval System  
**NPL** National Priorities List, as defined by CERCLA  
**NRC** U.S. Nuclear Regulatory Commission; also National Response Center (CERCLA)  
**NRD** Natural Resource Damage  
**NRDC** Natural Resources Defense Council  
**NSDWR** National Secondary Drinking Water Regulations, as defined in SDWA  
**NSPS** New Source Performance Standards, as defined in CAA  
**NSR** New Source Review, as defined in CAA  
**NSR/PSD** National Source Review/Prevention of Significant Deterioration, as defined in CAA  
**NTI** National Toxics Inventory  
**NTIS** National Technical Information Service, government publishing center  
**NTNCWS** Non-Transient Non-Community Water System, as defined in SDWA  
**NTP** National Toxicology Program  
**NTU** Nephelometric Turbidity Unit, a measure of water quality  
**NWPA** Nuclear Waste Policy Act

## O

**ODP** Ozone-Depleting Potential  
**ODS** Ozone-Depleting Substances  
**OECD** Organization for Economic Cooperation and Development  
**OEHA** Office of Environmental Health Hazard Assessment (USEPA)  
**OERR** Office of Emergency and Remedial Response (USEPA)  
**O&M** Operations and Maintenance  
**ONWI** Office of Nuclear Waste Isolation  
**OPA** Oil Pollution Act of 1990  
**ORE** Office of Regulatory Enforcement  
**ORC** Oxygen Release Compound, a groundwater remediation technology  
**ORM** Other Regulated Material, as defined in HMTA  
**ORP** Oxidation-Reduction Potential, a measure of water chemistry

**OSHA** Occupational Safety and Health Administration  
**OSWER** Office of Solid Waste and Emergency Response (USEPA)  
**OTA** Office of Technology Assessment, U.S. Congress  
**OTAG** Ozone Transport Assessment Group  
**OTC** Ozone Transport Commission  
**OTIS** Online Tracking Information System  
**OU** Operable Unit, as defined by CERCLA  
**OVA** Organic Vapor Analyzer  
**OVM** Organic Vapor Meter

## P

**P2** Pollution Prevention  
**PAG** Pesticide Assignment Guidelines  
**PAI** Performance Audit Inspection, as defined in CWA  
**PAM** Pesticide Analytical Manual  
**PA/SI** Preliminary Assessment/Site Investigation, as defined in CERCLA  
**PAT** Permit Assistance Team, as defined in RCRA  
**PATS** Pesticide Action Tracking System  
**PBT** Persistent Bioaccumulative Toxic pollutants  
**PCM** Phase Contrast Microscopy, an asbestos detection method  
**PCO** Pest Control Operator  
**PCSD** President's Council on Sustainable Development  
**PE** Professional Engineer, as licensed by an individual state or other nonfederal jurisdiction  
**PEL** Permissible Exposure Limit, as defined by OSHA  
**PG** Professional Geologist, as licensed by an individual state or other nonfederal jurisdiction  
**PHC** Principal Hazardous Constituent; also Petroleum Hydrocarbon  
**PHSA** Public Health Service Act  
**PIC** Products of Incomplete Combustion  
**PID** Photoionization Detector  
**PIGS** Pesticides in Groundwater Strategy  
**PIMS** Pesticide Incident Monitoring System  
**PIN** Pesticide Information Network  
**PIP** Public Involvement Program  
**PIRG** Public Interest Research Group  
**PIT** Permit Improvement Team  
**PLIRRA** Pollution Liability Insurance and Risk Retention Act  
**PLM** Polarized Light Microscopy  
**PM** Particulate Matter, a common air pollutant  
**PM<sub>2.5</sub>** Particulate Matter smaller than 2.5  $\mu\text{m}$  in diameter  
**PM<sub>10</sub>** Particulate Matter nominally 10  $\mu\text{m}$  and less in diameter  
**PM<sub>15</sub>** Particulate Matter nominally 15  $\mu\text{m}$  and less in diameter  
**PMEL** Pacific Marine Environmental Laboratory  
**PMN** Premanufacture Notification, as defined in TSCA  
**PMNF** Premanufacture Notification Form, as defined in TSCA  
**PNA** Polynuclear Aromatic Hydrocarbons  
**POC** Point of Compliance, as defined in RCRA  
**POE** Point of Exposure, a term used in risk assessment  
**POGO** Privately-Owned/Government-Operated  
**POHC** Principal Organic Hazardous Constituent  
**POM** Particulate Organic Matter; also Polycyclic Organic Matter  
**POP** Persistent Organic Pollutant  
**POTW** Publicly Owned Treatment Works, a municipal sewage treatment plant  
**POV** Privately Owned Vehicle  
**PPA** Pollution Prevention Act  
**ppb** parts per billion, a measure of concentration  
**PPE** Personal Protective Equipment  
**PPIC** Pesticide Programs Information Center  
**PPIS** Pesticide Product Information System  
**ppm** parts per million/parts per billion, a measure of concentration  
**ppmv** parts per million, by volume  
**ppmw** parts per million, by weight  
**PPSP** Power Plant Siting Program  
**ppt** parts per trillion, a measure of concentration  
**ppth** parts per thousand, a measure of concentration  
**PRA** Paperwork Reduction Act  
**PRATS** Pesticides Regulatory Action Tracking System  
**PRG** Preliminary Remediation Goal  
**PRN** Pesticide Registration Notice as defined in FIFRA  
**PRP** Potentially Responsible Party, as defined by CERCLA  
**PRZM** Pesticide Root Zone Model, as defined in FIFRA  
**PS** Point Source, as defined in CWA  
**PSA** Preliminary Site Assessment  
**PSC** Program Site Coordinator  
**PSD** Prevention of Significant Deterioration, as defined in CAA  
**PSES** Pretreatment Standards for Existing Sources, as defined in CWA  
**psi** pounds per square inch, a measure of pressure  
**psig** pressure per square inch gauge  
**PSM** Point Source Monitoring; also Process Safety Management  
**PSNS** Pretreatment Standards for New Sources, as defined in CAA  
**PTE** Potential to Emit, as defined in CAA  
**PTFE** Polytetrafluoroethylene (Teflon)  
**PUC** Public Utility Commission

**PVC** Polyvinyl Chloride  
**PWB** Printed Wiring Board  
**PWS** Public Water Supply/System  
**PWSS** Public Water Supply System

## Q

**QAC** Quality Assurance Coordinator  
**QAMIS** Quality Assurance Management and Information System  
**QAO** Quality Assurance Officer  
**QAPP** Quality Assurance Program (or Project) Plan  
**QA/QC** Quality Assistance/Quality Control  
**QAT** Quality Action Team  
**QBTU** Quadrillion British Thermal Units  
**QC** Quality Control  
**QCA** Quiet Communities Act  
**QCI** Quality Control Index  
**QCP** Quiet Community Program  
**QL** Quantification Limit, a laboratory instrument performance standard  
**QNCR** Quarterly Noncompliance Report  
**QUA** Qualitative Use Assessment

## R

**RA** Reasonable Alternative or Regulatory Alternatives or Regulatory Analysis or Remedial Action or Resource Allocation or Risk Analysis or Risk Assessment  
**RAATS** RCRA Administration Action Tracking System  
**RAC** Radiation Advisory Committee; Response Action Coordinator  
**RACM** Reasonably Available Control Measures, as defined in CAA  
**RACT** Reasonably Available Control Technology, as defined in CAA  
**rad** Radiation Absorbed Dose, a unit of measurement of radiation absorbed by humans  
**RAGS** Risk Assessment Guidelines for Superfund  
**RAMP** Rural Abandoned Mine Program  
**RAMS** Regional Air Monitoring System  
**RAO** Remedial Action Outcome  
**RAP** Remedial Action Plan, as defined in CERCLA  
**RAW** Remedial Action Workplan; also Removal Action Workplan  
**RBCA** Risk Based Corrective Action, a procedure to establish site-specific soil or groundwater cleanup standards  
**RC** Recovery Well, used in the extraction and treatment of contaminated groundwater  
**RCC** Radiation Coordinating Council  
**RCRA** Resource Conservation and Recovery Act  
**RCRIS** Resource Conservation and Recovery Information System  
**R&D** Research and Development  
**RD&D** Research, Development and Demonstration

**RDF** Refuse-Derived Fuel  
**RD/RA** Remedial Design/Remedial Action  
**RDV** Reference Dose Values, a term used in risk assessment  
**RDX** Research Derived Explosive  
**RE** Reasonable Efforts, a regulatory compliance term  
**REA** Registered Environmental Auditor (California)  
**REE** Rare Earth Elements  
**REEP** Review of Environmental Effects of Pollutants  
**REL** Recommended Exposure Limits or Levels; also Reference Exposure Level, terms used in risk assessment  
**REM** Roentgen Equivalent Man, a measure of radioactive dose  
**REM/FIT** Remedial/Field Investigation Team  
**REMS** RCRA Enforcement Management System  
**RF** Response Factor, a term used in risk assessment  
**RFA** Regulatory Flexibility Act or RCRA Facility Assessment  
**RFB** Request for Bid  
**RfC** Reference Concentration, a term used in risk assessment  
**RfD** Reference Dose Value, a term used in risk assessment  
**RFI** Remedial Field Investigation, as defined in RCRA  
**RFP** Request for Proposal  
**RHRS** Revised Hazard Ranking System, as defined in CERCLA  
**RI** Reconnaissance Inspection  
**RI** Remedial Investigation, as defined in CERCLA  
**RIA** Regulatory Impact Assessment  
**RIC** Radon Information Center  
**RICO** Racketeer Influenced and Corrupt Organizations Act  
**RI/FS** Remedial Investigation/ Feasibility Study, as defined in CERCLA  
**RIP** RCRA Implementation Plan  
**RISC** Regulatory Information Service Center  
**RJE** Remote Job Entry  
**RLL** Rapid and Large Leakage, a descriptor for release rates into the environment  
**RMCL** Recommended Maximum Contaminant Level, phrase being discontinued in favor of MCLG, as defined in SDWA  
**RME** Reasonable Maximum Exposure, a term used in risk assessment  
**RMP** Risk Management Plan  
**RNA** Ribonucleic Acid  
**ROADWAY** A computer model to predict pollutant concentrations near a roadway  
**ROC** Record of Communication  
**ROD** Record of Decision, as defined in CERCLA  
**ROG** Reactive Organic Gases  
**ROMCOE** Rocky Mountain Center on Environment

**ROP** Rate of Progress, a regulatory enforcement term

**ROPA** Record of Procurement Action, a government contracting term

**ROSA** Regional Ozone Study Area

**RP** Respirable Particulates or Responsible Party

**RQ** Reportable Quantities, as defined in CERCLA

**RQG** Reduced Quantity Generator, as defined by RCRA

**RRC** Regional Response Center

**RRT** Regional Response Team

**RSD** Risk-Specific Dose, a term used in risk assessment

**RTECS** Registry of Toxic Effects of Chemical Substances

**RTK** Right to Know

**RTP** Research Triangle Park

**RUP** Restricted Use Pesticide, as defined in FIFRA

**RWC** Residential Wood Combustion

## S

**S&A** Sampling and Analysis or Surveillance and Analysis

**SAB** Science Advisory Board

**SAC** Suspended and Cancelled Pesticides, as defined in FIFRA

**SAEWG** Standing Air Emissions Work Group

**SAIC** Special Agents in Charge

**SANE** Sulfur and Nitrogen Emissions

**SAP** Scientific Advisory Panel or Sampling and Analysis Plan

**SARA** Superfund Amendments and Reauthorization Act of 1986

**SAV** Submerged Aquatic Vegetation

**SCD/SWDC** Soil or Soil and Water Conservation District

**SCFM** Standard Cubic Feet per Minute

**SCR** Selective Catalytic Reduction, an air pollution control technology

**SCRC** Superfund Community Relations Coordinator

**SCSA** Soil Conservation Society of America

**SCSP** Storm and Combined Sewer Program

**SDWA** Safe Drinking Water Act

**SDWIS** Safe Drinking Water Information System

**SBS** Sick Building Syndrome

**SEA** State Enforcement Agreement

**SEA** State/EPA Agreement

**SEAM** Surface, Environment, and Mining

**SEAS** Strategic Environmental Assessment System

**SEDS** State Energy Data System

**SEIA** Socioeconomic Impact Analysis, as defined in NEPA

**SEM** Standard Error of the Means, a statistical measure of data quality

**SEP** Supplementary Environmental Project

**SEPC** State Emergency Planning Commission

**SEPWC** Senate Environment and Public Works Committee

**SETAC** Society for Environmental Toxicology and Chemistry

**SETS** Site Enforcement Tracking System

**SF** Standard Form or Superfund or Safety Factor

**SFA** Spectral Flame Analyzer, a laboratory analytical instrument

**SFFAS** Superfund Financial Assessment System

**SFIREG** State FIFRA Issues Research and Evaluation Group

**SHWL** Seasonal High Water Level

**SI** International System of Units or Site Inspection

**SIC** Standard Industrial Classification

**SICEA** Steel Industry Compliance Extension Act

**SIMS** Secondary Ion–Mass Spectrometry

**SIP** State Implementation Plan, as defined in CAA

**SITE** Superfund Innovative Technology Evaluation

**SLAMS** State/Local Air Monitoring Station

**SMCL** Secondary Maximum Contaminant Level, as defined in SDWA

**SMCRA** Surface Mining Control and Reclamation Act

**SME** Subject Matter Expert

**SMOA** Superfund Memorandum of Agreement

**SNAAQs** Secondary National Ambient Air Quality Standards, as defined in CAA

**SNARL** Suggested No Adverse Response Level, a term used in risk assessment

**SNC** Significant Noncompliers, a regulatory enforcement term

**SNUR** Significant New Use Rule, as defined in TSCA

**SOC** Synthetic Organic Chemicals

**SOCMI** Synthetic Organic Chemicals Manufacturing Industry

**SOW** Scope of Work

**SPCC** Spill Prevention, Containment, and Countermeasure, as defined in CWA

**SPE** Secondary Particulate Emissions, as defined in CAA

**SPLMD** Soil-pore Liquid Monitoring Device, a site characterization tool

**SPLP** Synthetic Precipitation Leaching Procedure, a laboratory method to test the leachability of contaminants from soil or solid waste

**SPS** State Permit System

**SQBE** Small Quantity Burner Exemption, as defined in RCRA

**SQG** Small Quantity Generator, as defined in RCRA

**SRAP** Superfund Remedial Accomplishment Plan

**SRC** Solvent-Refined Coal

- SRF** State Revolving Fund, as defined in CWA or SDWA
- SRM** Standard Reference Method, a compendium of laboratory analytical procedures
- SS** Setttable Solids or Suspended Solids
- SSA** Sole Source Aquifer
- SSAC** Soil Site Assimilated Capacity
- SSC** State Superfund Contracts
- SSEIS** Stationary Source Emissions and Inventory System, as defined in CAA
- SSO** Sanitary Sewer Overflow
- SSL** Soil Screening Levels, a term used in setting site-specific risk assessments
- STALAPCO** State and Local Air-Pollution Control Officials
- STAPPA** State and Territorial Air Pollution Program Administrators
- STAR** State Acid Rain projects
- STEL** Short Term Exposure Limit, as defined by OSHA
- STEM** Scanning Transmission-Electron Microscope
- STN** Scientific and Technical Information Network
- STORET** Storage and Retrieval of Water-Related Data
- STP** Sewage Treatment Plant or Standard Temperature and Pressure
- SUD** Safe Use Determination, as defined by TSCA
- SUP** Standard Unit of Processing
- SV** Sampling Visit or Significant Violator, regulatory enforcement terms
- SVE** Soil Vapor Extraction, a soil remedial technology
- SVOC** Semivolatile Organic Compounds
- SWA** Solid Waste Act; also known as RCRA
- SWAP** Source Water Assessment Program
- swarf** solid waste from metal grinding process
- SWC** Settlement with Conditions, a regulatory enforcement term
- SWDA** Solid Waste Disposal Act
- SWIE** Southern Waste Information Exchange
- SWMP** Storm Water Monitoring Program
- SWMU** Solid Waste Management Unit, as defined in RCRA
- SWPA** Source Water Protection Area, as defined in SDWA
- SWPPP** Storm Water Pollution Prevention Program
- SWQPPP** Source Water Quality Protection Partnership Petitions
- SWTR** Surface Water Treatment Rule, as defined in CWA
- SYSOP** Systems Operator
- T**
- TAD** Technical Assistance Document
- TAG** Technical Assistance Grant
- TAL** Target Analyte List
- TALMS** Tunable Atomic Line Molecular Spectroscopy, a laboratory analytical instrument
- TAMS** Toxic Air Monitoring System
- TAMTAC** Toxic Air Monitoring System Advisory Committee
- TAP** Technical Assistance Program
- TAPDS** Toxic Air Pollutant Data System
- TBC** To Be Considered a potential cleanup standard or goal, as defined in CERCLA
- TBT** Tributyltin, a wood preservative
- TC** Target Concentration or Toxicity Characteristics or Toxic Concentration
- TCF** Total Chlorine Free
- TCLP** Total Concentrate Leachate Procedure or Toxicity Characteristic Leachate Procedure, a procedure to assess the leachability of contaminants from soil or solid waste
- TCRI** Toxic Chemical Release Inventory, as defined in SARA
- TD** Toxic Dose
- TDS** Total Dissolved Solids, an indicator of water quality
- TEAM** Total Exposure Assessment Model
- TEC** Technical Evaluation Committee
- TED** Turtle Excluder Devices
- TEGD** Technical Enforcement Guidance Document
- TEL** Tetraethyl Lead
- TEP** Typical End-use Product or Technical Evaluation Panel
- TERA** TSCA Environmental Release Application
- TES** Technical Enforcement Support
- TGAI** Technical Grade of the Active Ingredient
- TGO** Total Gross Output
- TGP** Technical Grade Product
- THC** Total Hydrocarbons
- THM** Trihalomethane
- TIC** Tentatively Identified Compounds
- TIM** Technical Information Manager
- TIP** Technical Information Package
- TIP** Transportation Improvement Program
- TISE** Take It Somewhere Else, a common term used by opponents of a proposed disposal action
- TITC** Toxic Substance Control Act Interagency Testing Committee
- TKN** Total Kjeldahl Nitrogen
- TLV** Threshold Limit Value
- TMDL** Total Maximum Daily Limit or Total Maximum Daily Load, as defined in CWA
- TME** Test Marketing Exemption, as defined by TSCA
- TMRC** Theoretical Maximum Residue Contribution
- TNCWS** Transient Non-Community Water System
- TOA** Trace Organic Analysis
- TOB** Top of Bedrock

**TOC** Total Organic Carbon/Compound  
**TP** Total Particulates  
**TPH** Total Petroleum Hydrocarbons  
**TPQ** Threshold Planning Quantity, as defined by SARA  
**TPSIS** Transportation Planning Support Information System  
**TPY** Tons per Year  
**TQM** Total Quality Management  
**TRC** Technical Review Committee  
**TRD** Technical Review Document  
**TRI** Toxic Release Inventory  
**TRIP** Toxic Release Inventory Program  
**TRIS** Toxic Chemical Release Inventory System  
**TSCA** Toxic Substances Control Act  
**TSCC** Toxic Substances Coordinating Committee  
**TSDF** Technical Support Document; also Treatment, Storage, and Disposal  
**TSDF** Treatment, Storage, and Disposal Facility, as defined in RCRA  
**TSI** Thermal System Insulation  
**TSM** Transportation System Management  
**TSP** Total Suspended Particulates  
**TSS** Total Suspended (nonfilterable) Solids  
**TTO** Total Toxic Organics  
**TTHM** Total Trihalomethane  
**TVOC** Total Volatile Organic Compounds  
**TWA** Time Weighted Average, as defined by OSHA  
**TWS** Transient Water System, as defined by SDWA

## U

**UAC** User Advisory Committee  
**UAM** Urban Airshed Model  
**UAO** Unilateral Administrative Order  
**UAPSP** Utility Acid Precipitation Study Program  
**UAQI** Uniform Air Quality Index  
**UARG** Utility Air Regulatory Group  
**UCC** Ultra Clean Coal  
**UCL** Upper Control Limit, a laboratory instrument performance standard  
**UEL** Upper Explosive Limit  
**UF** Uncertainty Factor, a term used in risk assessment  
**UFFI** Urea-Formaldehyde Foam Insulation  
**UFL** Upper Flammability Limit  
**UGT** Underground Tank  
**UIC** Underground Injection Control, as defined by SDWA and RCRA  
**UM** Uniform Manifest, as defined by RCRA  
**UMTRCA** Uranium Mill Tailings Radiation Control Act  
**USC** Unified Soil Classification, a system used to describe soil features; also United States Code  
**USDA** United States Department of Agriculture

**USDW** Underground Sources of Drinking Water  
**UNECE** United Nations Economic Commission for Europe  
**UNEP** United Nations Environmental Programme  
**USEPA** United States Environmental Protection Agency  
**USFS** United States Forest Service  
**UST** underground storage tank  
**UTM** Universal Transverse Mercator, a grid coordinate system for maps  
**UTP** Urban Transportation Planning  
**UV** Ultraviolet  
**UVA, UVB, UVC** Ultraviolet Radiation Bands  
**UXO** Unexploded Ordnance  
**UZM** Unsaturated Zone Monitoring

## V

**VCP** Voluntary Cleanup Program  
**VE** Visual Emissions  
**VEO** Visible Emission Observation  
**VHAP** Volatile Hazardous Air Pollutant  
**VP** Vapor Pressure  
**VRP** Visibility Reducing Particles  
**VSD** Virtually Safe Dose  
**VSI** Visual Site Inspection  
**VSS** Volatile Suspended Solids

## W

**WA** Work Assignment  
**WADTF** Western Atmospheric Deposition Task Force  
**WAP** Waste Analysis Plan  
**WAVE** Water Alliances for Environmental Efficiency  
**WB** Wet Bulb, used in the measure of humidity  
**WCED** World Commission on Environment and Development  
**WDR** Waste Discharge Requirements  
**WENDB** Water Enforcement National Data Base  
**WERL** Water Engineering Research Laboratory  
**WET** Whole Effluent Toxicity, test  
**WHO** World Health Organization  
**WHPA** Wellhead Protection Area  
**WHPP** Wellhead Protection Program  
**WHWT** Water and Hazardous Waste Team  
**WICEM** World Industry Conference on Environmental Management  
**WL** Working Level, a radon measurement  
**WLA/TMDL** Wasteload Allocation/Total Maximum Daily Load, as defined in CWA  
**WMO** World Meteorological Organization  
**WPCF** Water Pollution Control Federation  
**WQA** Water Quality Act of 1987  
**WQS** Water Quality Standard

**WRC** Water Resources Council  
**WRDA** Water Resources Development Act  
**WRI** World Resources Institute  
**WSF** Water Soluble Fraction  
**WSRA** Wild and Scenic Rivers Act  
**WSTB** Water Sciences and Technology Board  
**WSTP** Wastewater Sewage Treatment Plant

**WWEMA** Waste and Wastewater Equipment  
Manufacturers Association  
**WWTP** Wastewater Treatment Plant

## X

**XRD** X-ray diffraction analysis  
**XRF** X-ray fluorescence analysis

# APPENDIX II

## CHRONOLOGY OF POLLUTION EVENTS

- 1783** *Laki, Iceland.* Laki volcanic eruption releases fluorine in such abundance that it poisons the vegetation, which in turn kills most of the livestock and 25 percent of the human population on Iceland
- 1815** *Tambora, near Java, Indonesia.* Tambora volcano releases such abundance of aerosols into the atmosphere that they cause global cooling and the “year without a summer” in 1816
- 1872** *Yellowstone, Wyoming.* Yellowstone National Park is established by an act of U.S. Congress
- 1890** **September 30.** *Yosemite, California.* Yosemite made a national park by an act of U.S. Congress
- 1892** **May 28.** John Muir establishes Sierra Club in San Francisco, California—the first environmental action organization in the United States
- 1899** U.S. Congress passes the Refuse Act, thereby allowing no refuse into United States marine waters
- 1906** *Witten, England.* Roburite factory chemical explosion
- 1908** **June 30.** *Tunguska, Siberia, Russia.* Comet or asteroid explodes above an uninhabited area of Siberia, flattening forests and killing all animals for 20 miles (32 km)
- 1910** Ringelmann’s Smoke Opacity Scale developed to rate thickness of smoke
- 1916** National Park Service established by an act of U.S. Congress
- 1918** *Newark, New Jersey.* Butterworth & Judson Chemical Works explosion  
*Oakdale, Pennsylvania.* Aetna Chemical Co. explosion
- 1919** **January 15.** *Boston, Massachusetts.* The great Boston Molasses Disaster
- 1930** **December 1–5.** *Meuse, Belgium.* Meuse Valley air pollution disaster from a temperature inversion trapping sulfur dioxide
- 1934–1940** *Southern Great Plains, United States.* Dust bowl drought and dust storms
- 1938** U.S. Congress enacts the Federal Food, Drug, and Cosmetic Act
- 1940–1960** *Minamata, Japan.* Chisso chemical plant produces severe mercury contamination and public health crisis
- 1944** *Los Angeles, California.* Los Angeles Bureau of Air Pollution Control established to combat rampant air pollution
- 1945** *Los Alamos, New Mexico.* Detonation of the first atomic devices  
*Hiroshima and Nagasaki, Japan.* Dropping of first uranium- and plutonium-based atomic bombs in warfare. Numerous humans exposed to severe radiation
- 1946–1958** *Bikini and Eniwetok Atolls.* Atomic and hydrogen bomb testing by the United States military
- 1947** *Los Angeles, California.* Los Angeles Air Pollution Control District established to battle air pollution with legal capability  
Federal Insecticide, Fumicide, and Rotenticide Act (FIFRA) signed into law
- 1948** **April 16.** *Texas City, Texas.* Explosion of 2,300 tons (2,030 metric tons) of ammonium nitrate causes a chain reaction killing 581 people, the deadliest industrial disaster in U.S. history.  
Nobel Prize awarded to Paul Muller for discovery that DDT could be used as a potent pesticide  
**October 26–30.** *Donora, Pennsylvania.* Donora air pollution disaster from industrial emissions from a zinc and steel plant during a temperature inversion

- 1949** *New York City, New York.* New York City Smoke Control Board established to address air pollution issues
- 1950** **November 24. Poza Rica, Mexico.** Poza Rica air pollution disaster of hydrogen sulfide gas from an oil refinery
- 1951** Rachel Carson publishes *The Sea around Us*
- 1952** **December 5–9. London, England.** “Killer Fog” strikes London from a temperature inversion killing upward of 12,000 people. Probably the worst strictly environmental disaster ever
- 1954** International Convention for the Prevention of Pollution of the Sea by Oil convened and regulations established
- 1955** *Pennsylvania, United States.* Pennsylvania passes the first air pollution law in the United States, primarily as the result of the Donora disaster  
Air Pollution Control Act (APCA) of 1955 signed into law as the first nationwide pollution legislation
- 1956** Clean Air Act of 1956 enacted in Great Britain largely as the result of the 1952 Killer Fog disaster
- 1957** The term *greenhouse effect* named and defined by Roger Revelle and Hans Suess
- 1959** Cranberries banned for Thanksgiving in the United States because of pesticide scare
- 1960** *California, United States.* California Motor Vehicle Pollution Control Act
- 1961** *Idaho Falls, Idaho.* Nuclear reactor explosion
- 1961–1970** *South Vietnam.* United States military forces use Agent Orange as a defoliant
- 1962** Rachel Carson publishes the American environmental landmark book *Silent Spring*.  
*London, England.* Pollution fog strikes again  
**May. Centralia, Pennsylvania.** Pennsylvania coal mine fires begin
- 1963** Clean Air Act of 1963 enacted by the U.S. Congress  
**January 29–February 13. New York City, New York.** New York City air pollution disaster
- 1964** **April 14.** Rachel Carson dies of breast cancer
- 1965** Clean Air Act of 1963 amended by the U.S. Congress  
Solid Waste Disposal Act (SWDA) enacted by the U.S. Congress
- 1966** Clean Air Act of 1963 amended by U.S. Congress again through pressure by environmentalists
- 1967** Clean Air Act of 1963 amended again  
**March 18. Cornwall, England.** *Torrey Canyon* oil spill in the Scilly Islands, the United Kingdom. The first major oil spill from a supertanker  
*Saudi Arabia.* Endrin poisoning of bread kills 26 and hospitalizes 874  
Air Quality Act of 1967 enacted by U.S. Congress
- 1968** United Nations Conference on the Human Environment
- 1969** Clean Air Act of 1963 amended by U.S. Congress  
Civil Liability Convention—Supertanker insurance and liability established for oil spills primarily in response to the *Torrey Canyon* disaster  
*Vancouver, Canada.* Greenpeace environmental advocacy organization established  
**January 29. Santa Barbara Channel, California.** Oil platform blowout and spill capture the attention of the American public and spur the environmental movement  
**June 22. Cleveland, Ohio.** Cuyahoga River fire, not very impressive but well covered by the media because of the interest in the environment generated by the Santa Barbara oil spill
- 1970** Clean Air Act of 1970 with sweeping changes in air quality legislation enacted by U.S. Congress  
Air Pollution Control Act of 1970 enacted by U.S. Congress  
*Port Hawkesbury, Nova Scotia, Canada.* *Arrow* tanker oil spill  
*Bangladesh.* Flood, water pollution, and disease resulting from the devastating cyclone and natural disaster of the century  
*St. Petersburg, Florida.* *Delian Apollon* tanker oil spill  
**January 1.** National Environmental Policy Act enacted by U.S. Congress  
**April 22.** First Earth Day in America attended by huge crowds in cities across the country galvanizes the environmental movement  
**December 2.** The U.S. Environmental Protection Agency founded by act of U.S. Congress  
*Monticello, Minnesota.* Nuclear reactor explosion

- International Oil Compensation Fund established to pay for oil spills
- 1972** DDT banned in the United States, fulfilling Rachel Carson's legacy  
*Glen Avon, California.* Stringfellow Quarry pollution—one of the major polluted sites in the country with no funds to remediate it  
 Marine Protection, Research, and Sanctuaries Act enacted by U.S. Congress to combat marine pollution  
 United Nations Conference on the Human Environment, first worldwide conference to address global environmental problems  
 Modernized version of the Federal Insecticide, Fumicide, and Rodenticide Act (FIFRA) to address pollution and public health issues  
**July 22. Portland, Maine.** *Tamano* tanker oil spill and cleanup
- 1972–1974** NIOSH National Occupational Hazard Survey undertaken to determine exposure of workers to hazardous substances in the workplace
- 1973** International Convention for the Prevention of Pollution (MARPOL) agreement among a group of nations to reduce marine (MAR) pollution (POL). This is the first MARPOL agreement  
 Benzidine banned in the United States for reasons of public health  
**December.** The initiation of the EPA-directed phased reduction of lead from all substances beginning with gasoline
- 1974** Safe Drinking Water Act enacted by U.S. Congress as a comprehensive program to safeguard water supplies. It is still in effect today
- 1975** *London, England.* United Nations Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter
- 1976** Chloroform banned from general usage in the United States  
 Resource Conservation and Recovery Act (RCRA) to regulate the disposal of solid waste passed by U.S. Congress into law  
 Toxic Substances Control Act passed by U.S. Congress specifically to address the removal of PCBs  
 Federal Food, Drug, and Cosmetic Act amended and modernized to address issues of chemical residues and exposure to hazardous substances
- May 12. La Coruña, Spain.** *Urquiola* supertanker oil spill
- July 10. Meda, Italy.** Seveso dioxin release—air pollution/industrial disaster
- December 15. New England, United States.** *Argo Merchant* supertanker accident and oil spill
- 1977** U.S. Congress declares national parks to be class I attainment zones for air pollution  
 DBCP pesticide banned from use in the United States  
 Lindane pesticide banned from use in the United States  
**February 25. Hawaii, United States.** *Hawaiian Patriot* tanker accident and oil spill
- April 22. North Sea.** Ekofisk oil well blowout and oil spill
- 1978** International Convention for the Prevention of Pollution (MARPOL) agreed upon by an international contingent. The second marine (MAR) pollution (POL) accord includes more stringent restrictions to cover some shortcomings of MARPOL 1973  
 Freon (CFC) 11 banned in the United States
- March 16. Ouessant, France.** *Amoco Cadiz* tanker accident and oil spill
- August 7. Niagara Falls, New York.** Love Canal pollution disaster declared a federal emergency by President Carter. This is the first time that this designation is used for anything other than a natural disaster. Probably the most extensively polluted site in the world. Revives the environmental movement
- 1979** Greenpeace International established. Shows the rapid growth of concern for environmental issues on a global basis  
**March 28. Middletown, Pennsylvania.** Three Mile Island nuclear power plant accident results in no deaths or damage to public health but heightens fears of the American public about the dangers of nuclear power
- June 3. Mexican Gulf of Mexico.** Ixtoc I blowout and oil spill, by far the largest oil spill in history up to that time and the third largest ever
- July 19. Tobago.** *Atlantic Empress* tanker accident and oil spill
- November 1. Houston, Texas, United States.** *Burmah Agate* tanker accident and oil spill

- 1979–1983 Bangladesh.** Drilled shallow-tube water well program initiated by the United Nations. The goal is to eliminate the rampant disease of surface water use but results in massive arsenic poisoning because it occurs naturally in the shallow aquifer in much of the country. Problem continues today
- 1980** TCE (trichloroethylene) restricted in the United States by EPA  
**Brooks, Kentucky.** Valley of the Drums future Superfund site established. Nearly as infamous as Love Canal, this pollution disaster also captures the attention of the American public  
 Low Level Radioactive Waste Policy Act of 1980 ratified by U.S. Congress and signed into law  
**April 21. Elizabeth, New Jersey.** Chemical Control Corp. fire and explosion of a profoundly polluted site also captures the attention of the American public  
**December 11.** Comprehensive Environmental Response Compensation and Liability Act (CERCLA) is signed into law by the president. It establishes the National Priorities List and Superfund largely as the result of the infamy of profoundly polluted sites such as Love Canal, Valley of the Drums, Times Beach, and Stringfellow. Provides public funds to clean up such sites and legal authority to pursue polluters
- 1981** EPA-directed removal of lead from foods  
**Oswego, New York.** Pollution Abatement Services Superfund site established and pollution addressed  
**October. New Jersey.** Price's Pit Superfund site established and addressed
- 1981–1983** NIOSH National Occupational Exposure Survey second and more comprehensive program undertaken to determine exposure of workers to hazardous substances in the workplace
- 1982** **Times Beach, Missouri.** Dioxin contamination and Superfund site declared. The most extreme measures ever taken in a cleanup; the whole town is evacuated, destroyed, and incinerated  
 Toxaphene pesticide banned from use in the United States
- 1983** **Shoshone County, Idaho.** Bunker Hill Complex Superfund Site established  
**Glen Avon, California.** Stringfellow Quarry finally declared a Superfund site; gained national attention years earlier for profound pollution
- February 4. Persian Gulf.** *Norwuz* blow-out and oil spill. One of several from the Iran-Iraq War, but this is the most significant by far
- August 6. Cape of Good Hope, South Africa.** *Castillo de Bellver* tanker accident and oil spill
- September 8. Woburn, Massachusetts.** Woburn Superfund site is established. Later achieves fame as the centerpiece of the movie *A Civil Action*
- 1984** **Minnesota, the United States.** Bell Lumber & Pole Superfund established  
 EDB (1,2-dibromoethane) pesticide an industrial chemical banned for use in the United States  
 RCRA Hazardous and Solid Waste Amendments enacted by U.S. Congress to address major shortcomings of the 1976 act
- September 21. Corvallis, Oregon.** United Chrome Superfund site is established
- December 3. Bhopal, India.** Union Carbide pesticide plant explosion is possibly the worst industrial accident ever in history. More than 3,500 killed
- 1985–2002** U.S. Geological Survey National Water Quality Assessment Program evaluates the contaminants and their concentrations in public water supplies across the United States to determine exposure
- 1986** Safe Drinking Water Act amended by U.S. Congress to address shortcomings of the original act  
**April 26. Pripyat, Ukraine.** Chernobyl nuclear power plant explosion and leak. The worst nuclear accident in history exposes most of northern Europe to dangerous levels of radiation
- August 21. Lake Nyos, Cameroon.** Volcanic gas cloud unexpectedly released from the bottom waters of the lake and asphyxiates an entire village, killing 1,700 people
- October 17.** Superfund Amendments and Reauthorization Act (SARA) enacted by U.S. Congress and signed into law. This act continues the Superfund program and expands its capacity and authority  
 Pesticides aldrin and dieldrin banned from use in the United States
- 1987** **Hill Air Force Base, Utah, United States.** Hill Air Force Base placed on Superfund list

- Montreal, Quebec, Canada.* Montreal Protocol developed. United Nations sponsors a convention to address the destruction of the stratospheric ozone layer by CFCs. Widely approved and enacted
- Colorado, United States.* Rocky Mountain Arsenal declared a Superfund site
- Marine Plastic Pollution and Control Act* approved by the U.S. Congress and signed into law
- 1987–1993** EPA Toxic Release Survey conducted to determine the amount of industrial release of pollutants to the environment in the United States
- 1987–1997** *Hinkley, California.* Pacific Gas & Electric pollution uncovered. Resulting lawsuit becomes the topic of the movie *Erin Brockovitch*
- 1988** *St.-Basile-le-Grand, Canada.* Toxic cloud develops from toxic waste dump
- Heptachlor pesticide banned for use in the United States
- Lead Contamination Control Act signed into legislation. Designed to remove all remaining common uses of lead
- Sofia, Bulgaria.* Sofia Protocol developed. United Nations sponsors a conference to reduce nitrogen oxides from the air on a global basis
- Ocean Dumping Ban Act and Public Vessel Medical Waste Anti-Dumping Act enacted largely to address arising issues of waste washing onto beaches
- April 14.** Pesticide chlordane banned in the United States. It was one of the last of the pesticides identified in the book *Silent Spring* to be banned
- 1989** *Anniston, Alabama.* Anniston Army Depot declared a Superfund site
- Earth in Balance* book, published by Al Gore. This is the future vice president's first book on the environment
- Ohio, United States.* Feed Materials Production Center declared a Superfund site
- Methylene chloride banned in hairspray in the United States
- The industrial chemical TCE (trichloroethylene) banned in the United States
- March 24.** *Valdez, Alaska.* Exxon Valdez supertanker grounding and oil spill in Prince George's Sound. Largest oil spill in the United States until 2010
- 1990** Clean Air Act of 1970 revised and expanded by U.S. Congress to attain current standards. Numerous jurisdictions are still in nonattainment with the new stringent regulations
- National Ambient Air Quality Standards (NAAQS) established for the United States
- Oil Pollution Control Act signed into law to control oil spills from tankers better. Largely enacted in response to the *Exxon Valdez* disaster
- Radiation Exposure Compensation Act signed into law. This bill is designed to compensate residents near nuclear test sites for health problems related to nuclear fallout
- Roger Revelle receives National Medal of Science for being the "grandfather of the greenhouse effect and global warming"
- 1991** *Oil fields, Kuwait.* Oil field fires and contamination purposefully started by retreating Iraqis during and after the Gulf War (Desert Storm). This is the largest environmental release of oil ever
- The pesticide endrin is banned in the United States
- Phenylmercuric acid banned from use in latex paints in the United States
- Philippines.* Mt. Pinatubo erupts, sending large amounts of sulfur into the atmosphere, which act as aerosols dispersing sunlight for the next year and contributing to air pollution
- 1992** International Oil Compensation Fund established by an international conference to help pay for oil spill damage and cleanup
- A U.S. congressional panel names Rachel Carson's *Silent Spring* "the most influential book of the last 50 years"
- Nuclear Test Ban Treaty ratified
- Rocky Mountain Arsenal Wildlife Refuge Act signed into legislation by the U.S. Congress to restore the area to natural conditions
- December 13.** *Galicia, Spain.* Aegean Sea supertanker accident and oil spill
- 1993** *Bartlesville, Oklahoma.* National Zinc designated a Superfund site
- January 5.** *Scotland, United Kingdom.* Braer supertanker accident and oil spill
- 1994** *Usnisk, Russia.* Oil spill from a broken pipeline in the Arctic
- Wetlands Act signed into legislation to preserve wetlands in the United States
- California Desert Protection Act enacted by U.S. Congress to prevent further environmental degradation of the fragile desert ecology

- 1995** EPA brownfields redevelopment program, officially known as the Small Business Liability & Brownfield Revitalization Act, signed into law. This legislation makes it possible for profoundly polluted sites that would never achieve “greenfield” status to be partly remediated and restored to useful service  
Paul Crutzen, Mario Molina, and Sherwood Rowland collaboratively receive the Nobel Prize in chemistry for their work documenting destruction of the stratospheric ozone layer primarily by CFCs  
**December 31.** Lead banned for use in gasoline. Although it had been eliminated in most commercially available vehicles long before this, the last minor uses are finally eliminated as well
- 1996** The industrial chemical and VOC TCA-(1,1,1-trichloroethane) is banned  
Safe Drinking Water Act amended by U.S. Congress to achieve the current rigorous standards. It is the current version
- 1997** Annex VI of the MARPOL agreement is enacted to control diesel exhaust in the marine environment  
**December 11.** *Kyoto, Japan.* Kyoto Protocol is drafted and adopted in a United Nations conference to reduce greenhouse gases. Several countries have yet to sign, including the United States
- 1998** Louisiana-Pacific Corp. loses largest air pollution violation case in Clean Air Act history
- 1999** **March.** *New Mexico, United States.* Waste Isolation Pilot Plant (WIPP) established as a national repository for transuranic waste  
**December 12.** *Brittany, France.* Erika supertanker accident and oil spill
- 2001** **September 11.** *New York City, New York.* World Trade Center disaster is caused by terrorists flying commercial airliners into both towers of the World Trade Center and destroying them. The act kills nearly 3,000 American citizens and creates a toxic cloud that still affects exposed rescue, relief, and cleanup workers
- 2002** The United States ends domestic production of asbestos  
**February 22.** The United States enacts the Arsenic Rule, which limits arsenic to 10 parts per billion in water  
**November 13–19.** *Galicia, Spain.* Prestige supertanker accident and oil spill
- 2003** **July 27.** *Port Karachi, Pakistan.* Tasman Spirit supertanker accident and oil spill
- 2004** The industrial chemical Diazinon is heavily restricted in the United States  
**November.** The Regional Greenhouse Gas Initiative is adopted by nine northeastern states (Maine, Massachusetts, New Hampshire, Vermont, Rhode Island, Connecticut, New York, New Jersey, and Delaware) to reduce greenhouse gas production under the terms of the Kyoto Protocol
- 2005** Cap and trade plan for mercury emission from older coal-burning power plants adopted by the George W. Bush administration. Creates significant loopholes for the most polluting power plants, which otherwise would have had to be shut down or refitted  
The Energy Policy Act of 2005 is enacted. It calls for a stepped phaseout of MTBE  
**March 23.** *Texas City, Texas, the United States.* Explosion and fire at a BP oil refinery kills 15 and injures 170 people  
**August 29.** *New Orleans, Louisiana.* Hurricane Katrina destroys the American city killing more than 1,400 residents and creating a “toxic soup” of pollutants and waste in the flooding salt water  
**November 13.** *Harbin, China.* A chemical factory spills 100 tons (90 metric tons) of benzene into the Songhau River, killing five people and causing an international incident with Russia
- 2006** *An Inconvenient Truth* published by former vice president Al Gore about the dangers of greenhouse gases and global warming. A documentary of the same name is also produced
- 2007** CO<sub>2</sub> is declared a pollutant that could be regulated by the EPA  
The documentary *An Inconvenient Truth* by Al Gore wins two Academy Awards  
Al Gore receives the Nobel Prize in peace for his work on raising the public awareness of the problems of global warming and greenhouse gases  
*Nye County, Nevada.* Scheduled date for the opening of the Yucca Mountains high-level nuclear waste repository
- 2008** *Sichuan, China.* Massive earthquake (M-8) strikes Sichuan, China, and causes major environmental damage  
**December 22.** *Kingston, Tennessee.* Large release of coal ash into the Tennessee River.

- 2009** *Copenhagen, Denmark.* UN Copenhagen Accord signed to supersede Kyoto Protocol. Designed to reduce CO<sub>2</sub> emissions by 2020
- 2010** **January 12.** *Port-au-Prince, Haiti.* Massive earthquake (M-7.2) strikes Haiti, leaving 200,000 people dead and causing major environmental damage  
**April 15–20.** Emissions of ash from volcano Eyjafjallajökull close airports across Europe  
**April 20.** *Louisiana, Gulf of Mexico, United States.* Explosion and fire on the Deepwater Horizon drilling platform releases an estimated 204 million gallons (772.2 million L) of oil into the Gulf of Mexico over the next three months. Declared the worst environmental disaster in U.S. history  
**October 5.** *Kolontar, Hungary.* Chemical spill from aluminum plant kills seven and injures 150 people.  
**December.** *Ringwood, New Jersey.* Ford Motor Company ordered by EPA to return to the Superfund site it created to remove thousands of tons of additional toxic paint sludge
- 2011** **January.** *Spelter, West Virginia.* DuPont pays \$70 million to clean up a zinc smelter and 100-foot (30-m) tailings pile and fund long-term medical monitoring of residents
- March 11.** *Honshu, Japan.* A magnitude 9.0 earthquake and resulting tsunami strike northeastern Japan, killing more than 20,000 people and damaging four nuclear power plants. The Fukushima plant released radiation and was the second-worst civilian nuclear accident ever
- March 16.** *Tristan da Cunha Islands.* Tanker MS *Olivia* spills 800 tons (726 metric tons) of fuel oil into ecologically sensitive area of southernmost Atlantic Ocean
- April 25–29.** *Geneva, Switzerland.* Pesticide endosulfan is officially banned on a worldwide basis by international agreement by the Stockholm Convention of the Review Committee on Persistent Organic Pollutants
- April 27.** *Southern United States.* One of the worst outbreaks of tornadoes in history kills more than 300 people and causes extensive pollution problems
- Nye County, Nevada.** Scheduled date for the opening of the Yucca Mountains high-level nuclear waste repository, if it is not scuttled by congressional debates in 2010–11

2017

# APPENDIX III

## GLOSSARY

**abandoned well** a well whose use has been permanently discontinued or is in a state of such disrepair that it cannot be used for its intended purpose. The closure of wells is regulated by local agencies. For oil wells, the top 50 feet (15.4 m) must be pumped full of cement

**abatement** reducing the degree or intensity of, or eliminating, pollution of water, soil, air, or structures

**abiotic** any nonliving component of the environment

**absorbed dose** in an exposure assessment, the amount of a substance that penetrates an exposed organism's defensive mechanisms such as skin, lung tissue, or gastrointestinal tract through physical or biological processes. Synonymous with *internal dose*

**absorption** the uptake of water, other fluids, or dissolved chemicals by a cell or an organism

**absorption barrier** the parts of an organism that retard the penetration, uptake, or exchange of various substances (e.g., skin, lung tissue, and gastrointestinal tract wall)

**abyssal plain** a flat, level, mostly featureless part of the ocean floor present between the midoceanic ridge and the continental rise

**acclimatization** the physiological and behavioral adjustments made by an organism to changes in its environment

**accuracy** a measurement in which the determined quantity is exactly correct for the individual determination whether it can be repeated or not. See PRECISION

**acid** a corrosive and dissolving solution with a pH less than 7. The lower the pH, the stronger the acid will be

**acid deposition** a complex chemical and atmospheric phenomenon that occurs when emissions of sulfur and nitrogen compounds and other substances are transformed by chemical processes in the atmosphere, often far from the

original sources, and then deposited on Earth in either wet or dry form. The wet forms, popularly called acid rain, can fall to earth as rain, snow, or fog. The dry forms are acidic gases or particulates

**acid neutralizing capacity** measure of the ability of a base (e.g., water or soil) to resist a decrease in pH if mixed with a solution or solid

**acid rain** See ACID DEPOSITION

**action levels** concentrations of pesticides recommended by U.S. Environmental Protection Agency for enforcement by the Food and Drug Administration and the U.S. Department of Agriculture if residues are present in food or animal feed as a result of other than the direct application of the pesticide (see TOLERANCES). Also, in the Superfund program, the existence of a contaminant concentration in the environment at levels sufficient to warrant enforcement action or trigger a response under SARA or the NCP

**activated carbon** a highly adsorbent form of carbon utilized to remove odors and toxic substances from liquid or gaseous emissions. It is commonly used to adsorb (filter out or capture) dissolved organic matter from drinking water as granulated activated carbon (GAC)

**activator** a chemical added to a pesticide to increase its effectiveness

**active ingredient** in any pesticide product, the active ingredient is the chemical compound that does the actual killing or otherwise controls, target pests. Pesticides are regulated primarily on the basis of active ingredients

**acute effect** an adverse effect on any living organism that results from a single significant dose of a chemical compound. These severe symptoms tend to develop rapidly

**acute exposure** a single exposure to a toxic substance that may result in severe biological harm (illness) or death. Acute exposures are usually characterized as lasting no longer than a day, as

compared to longer, continuing exposure over time. See CHRONIC EXPOSURE

**acute toxicity** the ability of a substance to cause severe biological harm or death soon after a single exposure or dose. Also used to describe any poisonous effect resulting from a single short-term exposure to a toxic substance. See TOXICITY

**adaptation** changes in an organism's physiological structure or function or habits that allow it to survive in new surroundings

**add-on control device** an air pollution control device such as carbon absorber or incinerator that reduces the pollution in an exhaust gas. The added control device usually does not affect the process being controlled

**adhesive forces** the attractions that molecules of one substance exert on those of a different substance

**administered dose** in exposure assessment, the amount of a substance given to a test subject (human or animal) to determine dose-response relationships. Since exposure to chemicals is usually inadvertent, this quantity is often called potential dose

**Administrative Order** a legal document signed by the U.S. Environmental Protection Agency directing an individual, business, or other entity to take corrective action or refrain from an activity. It describes the violations and actions to be implemented and can be enforced in court

**Administrative Order on Consent** a legal agreement signed by the U.S. Environmental Protection Agency and an individual, business, or other entity through which the violator agrees to pay for correction of violations, take the required corrective or cleanup actions, or refrain from an activity. It describes the actions to be taken, may be subject to a comment period, applies to civil actions, and can be enforced in court

**Administrative Procedures Act** a law that explicitly defines the procedures and requirements related to the promulgation of regulations

**Administrative Record** all documents that the U.S. Environmental Protection Agency considered or relied on in selecting the response action at a Superfund site, culminating in the record of decision (ROD) for remedial action or an action memorandum for removal of pollution and polluted materials

**adsorption** removal of a pollutant from air or water by collecting the pollutant on the surface of a solid material. For example, activated carbon removes (adsorbs) organic matter from wastewater

**adulterants** chemical impurities or substances that by law do not belong in a food or pesticide

**advanced treatment** a level of wastewater treatment more stringent than secondary treatment. It requires an 85 percent reduction in conventional pollutant concentration or a significant reduction in nonconventional pollutants concentration. See TERTIARY TREATMENT

**advanced wastewater treatment** any treatment of sewage that goes beyond the secondary or biological water treatment stage and includes the removal of nutrients such as phosphorus and nitrogen and a high percentage of suspended solids. See PRIMARY TREATMENT; SECONDARY TREATMENT

**advection** the horizontal component of a convection current in air (e.g., wind)

**advisory** a nonregulatory document that communicates risk information to those who may have to make risk management decisions (e.g., fish consumption advisory)

**aerated lagoon** a holding and/or treatment pond that speeds up the natural process of biological decomposition of organic waste by stimulating the growth and activity of aerobic bacteria that degrade organic waste through the rapid infusion of air into the wastewater

**aeration** a process that promotes biological degradation of organic matter in water. The process may be passive (as when waste is exposed to air) or active (as when a mixing or bubbling device introduces the air)

**aerobic** life or processes that require, or are not destroyed by, the presence of oxygen. See ANAEROBIC

**aerobic treatment** process by which microbes decompose complex organic compounds in the presence of oxygen and use the liberated energy for reproduction and growth. Such processes take place in aeration tanks, trickling filtration systems, and rotating biological contactors

**aerosol** small droplets or particles suspended in the atmosphere that can reflect and disperse incoming solar radiation. They are usually emitted naturally (in volcanic eruptions) and as the result of anthropogenic (human) activities such as burning fossil fuels. *Aerosol* is also a term used to describe the pressurized gas used to propel substances out of a container

**affected public** the people who live and/or work near a hazardous waste site. Also, the human population adversely impacted after exposure to a toxic pollutant in food, water, air, or soil

**afterburner** an air pollution control device on an incinerator in which the combustion gases

are made to pass through its flame in order to remove smoke and odors

**agent** any physical, chemical, or biological entity that can be harmful to an organism. Also called stressor

**Agent Orange** a toxic herbicide and defoliant used in the Vietnam conflict, containing 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and 2,4-dichlorophenoxyacetic acid (2,4-D) with trace amounts of dioxin

**agricultural pollution** farming wastes, including runoff and leaching of pesticides and fertilizers; erosion and dust from plowing; improper disposal of animal manure and carcasses; crop residues; and debris

**agricultural waste** poultry and livestock manure and residual materials in liquid or solid form generated from the production and marketing of poultry, livestock, or fur-bearing animals; also includes grain, vegetable, and fruit harvest residue

**agroecosystem** land used for crops, pasture, and livestock; the adjacent uncultivated land that supports other vegetation and wildlife; and the associated atmosphere, underlying soils, groundwater, and drainage networks

**airborne particulates** total suspended particulate matter found in the atmosphere as solid particles or liquid droplets. Chemical composition of particulates varies widely, depending on location and time of year. Sources of airborne particulates include dust, emissions from industrial processes, combustion products from the burning of wood and coal, combustion products associated with motor vehicle or nonroad engine exhausts, and reactions to gases in the atmosphere

**airborne release** release of any pollutant into the air

**air contaminant** any individual or combination of particulate matter or gas other than water vapor present in the atmosphere. See AIR POLLUTANT

**air curtain** a method of containing oil spills. Air bubbling through a perforated pipe causes an upward water flow that slows the spread of oil. It can also be used to stop fish from entering polluted water

**air mass** a large volume of air in the atmosphere with certain meteorological or pollution characteristics (e.g., smog, particulate) that reflect its location of origin (e.g. Canadian air mass, Gulf of Mexico air mass). The characteristics can change as the air mass moves away

**air permeability** permeability of soil with respect to air. It is important to the design of soil-gas

surveys. Measured in darcy or centimeter per second

**air plenum** any space used to convey air in a building, furnace, or structure. The space above a suspended ceiling is often used as an air plenum

**air pollutant** any substance in air that could, in high enough concentration, harm people, animals, vegetation, or material. It can be in the form of individual or groups of solid particles, liquid droplets, or gases but excludes pollen, fog, and dust, which are of natural origin. Air pollutants are often grouped in categories for ease in classification: solids, sulfur compounds, volatile organic chemicals, particulate matter, nitrogen compounds, oxygen compounds, halogen compounds, radioactive compound, and odors

**air pollution control device** mechanism or equipment that cleans emissions generated by a pollution source and removes the pollutants that would otherwise be released to the atmosphere

**air pollution episode** a period of abnormally high concentration of air pollutants, often due to low winds and temperature inversion, that can cause illness and death

**Air Quality Criteria** the levels of pollution and lengths of exposure to certain contaminants above which adverse health and welfare effects may occur

**Air Quality Standards** the level of pollutants prescribed by federal or state regulations that is not to be exceeded during a given time in a defined area

**air sparging** injecting air or oxygen into an aquifer to strip or flush volatile contaminants as air bubbles up through the groundwater to be captured by a vapor extraction system

**air stripping** a treatment system that removes volatile organic compounds (VOCs) from contaminated groundwater or surface water by forcing an airstream through the water and causing the compounds to evaporate

**air toxics** any air pollutant for which a National Ambient Air Quality Standard (NAAQS) does not exist (other than ozone, carbon monoxide, PM10, sulfur dioxide, nitrogen oxide) that may reasonably be anticipated to cause cancer; respiratory, cardiovascular, or developmental effects; reproductive dysfunctions; neurological disorders; heritable gene mutations; or other serious or irreversible chronic or acute health effects in humans

**alachlor** a dangerous herbicide, marketed under the trade name Lasso, used mainly to control weeds in corn and soybean fields

**Alar** trade name for daminozide, a pesticide that makes apples redder, firmer, and less likely to drop off trees before growers are ready to pick them. It also is used to a lesser extent on peanuts, tart cherries, Concord grapes, and other fruits

**aldicarb** an insecticide sold under the trade name Temik. It is made from ethyl isocyanate

**algae** simple rootless plants that grow in sunlit waters in proportion to the amount of available nutrients. They can affect water quality adversely by lowering the dissolved oxygen in the water. They are food for fish and small aquatic animals

**algal blooms** sudden quick growth of algal population in an area, which can adversely affect water quality and indicate potentially serious changes in local water chemistry

**algicide** substance or chemical used specifically to kill or control algae

**aliquot** a measured portion of a sample taken for analysis. One or more aliquots make up a sample

**alkaline** the condition of water or soil that contains a sufficient amount of alkali elements and compounds to raise the pH above 7.0

**alkalinity** the capacity of bases to neutralize acids. An example is lime added to lakes to decrease acidity

**allergen** a substance that causes an allergic reaction in individuals sensitive to it

**alloy** a mixture of a metal and one or more additional elements, most commonly additional metals

**alpha particle** a high-energy radioactive particle (two protons and two neutrons) produced by the radioactive decay of certain isotopes

**alternative fuels** substitutes for traditional liquid, oil-derived motor vehicle fuels such as gasoline and diesel. Includes mixtures of alcohol-based fuels with gasoline, methanol, ethanol, compressed natural gas, and others

**ambient air** any unconfined portion of the atmosphere, open air, or surrounding air

**ambient measurement** a measurement of the concentration of a substance or pollutant within the immediate environs of an organism; taken to relate it to the amount of possible exposure

**ambient temperature** temperature of the surrounding air or other medium

**amensalism** relationship between species in which one organism is harmed and the other is unaffected (e.g., large trees shading and preventing or limiting the growth of small trees)

**amphibole** a group of ferromagnesian silicate minerals found in crystalline rocks that includes certain forms of asbestos (crocidolite and tremolite)

**anaerobic** a life or process that operates in the absence of oxygen

**anaerobic decomposition** degradation or the reduction of the net energy level and change in chemical composition of organic matter caused by microorganisms in an oxygen-free environment

**analyte** a substance whose concentration is being determined, usually through a laboratory test

**animal dander** tiny scales of animal skin, a common indoor air pollutant

**animal studies** investigations using animals as surrogates for humans with the expectation that the results are pertinent to humans

**anion** a negatively charged ion, either a single element or compound by gain of electrons. Reacts with a cation to form a stable compound

**anisotropy** the condition of a material in which the properties are not isotropic in their distribution (e.g., layering). In hydrology, the conditions under which one or more hydraulic properties of an aquifer vary from a given reference point

**annular space, annulus** the open space between two concentric tubes or casings, or between the casing and the borehole wall of a soil-boring or soil-monitoring well

**antagonism** interference or inhibition of the effect of one chemical by the action of another

**antigen** a substance that when introduced into the body stimulates the production of an antibody. Antigens include toxins, bacteria, foreign blood cells, and the cells of transplanted organs

**antimicrobial** an agent that kills microbes

**Applicable or Relevant and Appropriate Requirements (ARARs)** any state or federal statute that pertains to protection of human life and the environment in addressing specific conditions or use of a particular cleanup technology at a Superfund site

**applied dose** in exposure assessment, the amount of a substance in contact with the primary absorption boundaries of an organism (e.g., skin, lung tissue, gastrointestinal tract) and available for absorption

**aquaculture** the raising of aquatic organisms for food in controlled environments (e.g., fish farming)

**aqueous** a solution or other medium that is volumetrically dominated by water

**aqueous solubility** the maximal amount of a chemical (solute) that will dissolve in pure water at a given temperature, pressure, and other constraints

**aquifer test** a test to determine hydraulic properties (yield, flow rate) of an aquifer

**aquitard** geological formation that may contain groundwater but is not capable of transmitting significant (usable) quantities of it under normal hydraulic gradients

**architectural coatings** coverings such as paint and roof tar that are used on exteriors of buildings to protect them from detrimental effects of weather and organisms

**Area of Concern (AOC)** any existing or former location where hazardous substances, hazardous wastes, or pollutants are or were known or suspected to have been discharged, generated, manufactured, refined, transported, stored, handled, treated, or disposed, or where hazardous substances, hazardous wastes, or pollutants have or may have migrated. Areas of concern are targeted for evaluation as part of a site investigation

**aromatics** a type of hydrocarbon, such as benzene or toluene, with a specific type of ring structure. Aromatics are sometimes added to gasoline in order to increase octane. Some aromatics are toxic

**arsenicals** pesticides containing arsenic

**artesian (aquifer or flowing well)** water held under enough pressure in an aquifer confined by impermeable layers that it can flow to the surface if penetrated by a well

**asbestos abatement** procedures to control fiber release from asbestos-containing materials in a building or to remove them entirely, including removal, encapsulation, repair, enclosure, encasement, and operations and maintenance programs

**Asbestos-Containing Waste Materials (ACWM)** mill tailings or any waste that contains commercial asbestos and is generated by a source covered by the Clean Air Act Asbestos NESHAPS

**asbestosis** a disease associated with inhalation of asbestos fibers. The disease makes breathing progressively more difficult and can be fatal

**ash** the chemical product remaining after complete combustion of a substance

**assay** a test for a specific chemical, microbe, or effect as a proportion of an enclosing material

**assimilative capacity** the capacity of a natural body of water to receive wastewaters or toxic materials without deleterious effects and without damage to aquatic life or humans who consume the water

**atmosphere** a mixture of gases, mostly nitrogen and oxygen, with smaller amounts of argon, carbon dioxide, and other gases

**atom** the smallest unit or amount of an element

**atomic mass** the total number of protons and neutrons in an atom; each has 1 atomic mass unit

**atomic number** the number of protons in the nucleus of an atom or electrons in the shells

**attainment area** an area considered to have air quality as good as or better than the National Ambient Air Quality Standards, as defined in the Clean Air Act for individual pollutants. An area may be an attainment area for one pollutant and a nonattainment area for others

**attenuation** the process by which a compound is reduced in concentration over time, through absorption, adsorption, degradation, dilution, and/or transformation

**attractant** a chemical or agent that lures insects or other pests by stimulating their sense of smell

**attrition** wearing or grinding down of a substance by friction. Dust from such processes contributes to air pollution

**autotroph (primary producer)** an organism that uses sunlight and non-carbon-hydrogen chemical compounds in the environment to make its own food

**background level** the concentration of a substance in an environmental medium (air, water, or soil) that occurs naturally or is not the result of human activities. In exposure assessment, background level is the concentration of a substance in a defined control area, during a fixed period before, during, or after a data-gathering operation

**back pressure** a pressure that can cause water to flow backward into the water supply when a user's wastewater system is at a higher pressure than the public system

**backwashing** reversing the flow of water back through the filter medium to remove entrapped solids and renew its capacity to act as a filter

**backyard composting** diversion of organic food waste and yard trimmings from the municipal waste stream by treating them on private property (backyard) through controlled decomposition of organic matter by bacteria and fungi into a humuslike product. It is considered source reduction, not recycling, because the composted materials never enter the municipal waste stream

**BACT—Best Available Control Technology** an emission limitation based on the maximal degree of emission reduction (considering energy, environmental, and economic impacts) achievable through application of production processes and available methods, systems, and techniques. BACT does not permit emissions in excess of those allowed under any applicable Clean Air Act provisions

**bacteria** (singular bacterium) microscopic single-celled organisms that can aid in pollution control by metabolizing organic matter in sewage, oil spills, or other pollutants. Bacteria in soil, water, or air also can cause diseases that harm humans, animals, and plants

**bactericide** a pesticide used to control or destroy bacteria, typically in the home, schools, or hospitals

**baffle** a flat board or plate, deflector, guide, or similar device constructed or placed in flowing air, water, or slurry systems to cause more uniform flow velocities to absorb energy and to divert, guide, or agitate the flowing material

**baghouse filter** large fabric bag, usually made of glass fibers, used to eliminate intermediate and large (greater than 20 microns in diameter) particles. This device operates as the bag of an electric vacuum cleaner does, passing the air and smaller particles while entrapping the larger ones

**bailer** a pipe with a one-way (check) valve at the lower end, used to remove slurry from the bottom or side of a well as it is being drilled, or to collect groundwater samples from wells or open boreholes

**baling** compacting and tying solid waste into blocks to reduce volume and simplify handling

**bank** the rising slope bordering the side of a stream channel

**barrel sampler** open-ended steel tube that is driven into the ground to collect soil samples with minimal disruption to the structure

**bar screen** in wastewater treatment, a device used to remove large solids

**basal application** in pesticides, the application of a chemical on plant stems or tree trunks just above the soil line

**base** a substance that provides hydroxide anions and has a pH above 7.0

**bean sheet** common term for a pesticide data package record

**bed load** sediment particles resting on or near the channel bottom that are pushed or rolled along by the flow of water

**bench-scale tests** laboratory testing of potential cleanup technologies. See TREATABILITY STUDIES

**benthic or benthos** an organism that feeds on the sediment at the bottom of a water body such as an ocean, lake, or river

**bentonite** a colloidal clay that expands when moist, commonly used to provide a tight seal around a well casing

**Best Available Control Measures (BACM)** a term used to refer to the most effective mea-

asures (according to U.S. Environmental Protection Agency guidance) for controlling small or dispersed particulates and other emissions from sources such as roadway dust, soot, and ash from woodstoves, and open burning of brush, timber, grasslands, or trash

**Best Available Control Technology (BACT)** the most stringent technology available for controlling emissions; major sources are required to use BACT, unless it can be demonstrated that it is not feasible for energy, environmental, or economic reasons

**Best Demonstrated Available Technology (BDAT)** as identified by the U.S. Environmental Protection Agency, the most effective commercially available means of treating specific types of hazardous waste. The BDATs may change with advances in treatment technologies

**Best Management Practice (BMP)** methods that have been determined to be the most effective, practical means of preventing or reducing pollution from nonpoint sources

**beta particle** a high-energy electron emitted by the nucleus of certain types of radioactive atoms

**bioaccumulants** substances that increase in concentration in living organisms as they take in contaminated air, water, or food because the substances are very slowly metabolized or excreted. See BIOLOGICAL MAGNIFICATION

**bioassay** a test to determine the relative strength of a substance by comparing its effect on a test organism with that of a standard preparation

**bioavailability** degree of a substance's ability to be absorbed and to interact with an organism's metabolism

**biodegradable** capable of being decomposed by microorganisms under natural conditions

**biodiversity** refers to the variety and variability among living organisms and the ecological complexes in which they occur. Diversity can be defined as the number of different items and their relative frequencies. For biological diversity, these items are organized at many levels, ranging from complete ecosystems to the biochemical structures that are the molecular basis of heredity. Thus, the term encompasses different ecosystems, species, and genetic makeups

**biological contaminants** living organisms or derivatives (e.g., viruses, bacteria, fungi, and mammal and bird antigens) that can cause harmful health effects when inhaled, swallowed, or otherwise taken into the body

**biological control** in pest control, the use of animals and organisms that eat or otherwise kill or outcompete pests

**biological integrity** the ability to support and maintain balanced, integrated functionality in the natural habitat of a given region. The concept is applied primarily in drinking water management

**biologically effective dose** the amount of a deposited or absorbed compound reaching the cells or target sites where the effect will occur, or where the chemical interacts with a membrane

**biological measurement** a measurement taken in a biological medium. For exposure assessment, it is related to the established internal dose of a compound

**biological medium** one of the major components of an organism (e.g., blood, fatty tissue, lymph nodes, or breath) in which chemicals can be stored or transformed

**biological oxidation** decomposition of complex organic materials by microorganisms. Occurs in self-purification of water bodies and in activated sludge wastewater treatment

**biological oxygen demand (BOD or BOD5)** an indirect measure of the concentration of biologically degradable material present in organic wastes. It usually reflects the amount of oxygen consumed in five days by biological processes breaking down organic waste

**biological pesticides** certain microorganisms, including bacteria, fungi, viruses, and protozoa, that are effective at controlling pests. These agents usually do not have toxic effects on animals and people and do not leave toxic or persistent chemical residues in the environment

**biological stressors** organisms accidentally or intentionally dropped into habitats in which they did not naturally evolve (e.g., gypsy moths, Dutch elm disease, certain types of algae, and bacteria) but will damage and degrade

**biological treatment** a treatment technology that uses bacteria to consume organic waste

**biomass** all of the living material in a given area; often refers to vegetation

**biome** entire community of interacting living organisms that have adapted to a single major ecological area

**biomonitoring** the use of living organisms to test the suitability of treated wastewater for discharge into receiving waters and to test the quality of such waters downstream from the discharge

**biosphere** the portion of Earth and its hydrosphere and atmosphere that can support life

**biostabilizer** a machine that converts solid waste into compost by grinding and aeration

**biota** the animal and plant life (all living organisms) of a given region

**biotechnology** techniques and processes that use living organisms or parts of organisms to produce a variety of products (from medicines to industrial enzymes), to improve plants or animals, to develop microorganisms to remove toxics from bodies of water, or to act as pesticides

**biotic community** a naturally occurring assemblage of plants and animals that live in the same environment and are mutually sustaining and interdependent

**biotransformation** conversion of a substance into other compounds by organisms; includes biodegradation

**blackwater** water that contains animal, human, or food waste

**bloom** a proliferation of algae and/or higher aquatic plants in a body of water; often related to pollution, especially when pollutants accelerate growth

**body burden** the amount of a chemical stored in the body at a given time, especially a potential toxin in the body as the result of exposure

**bog** a type of wetland that accumulates appreciable peat deposits. Bogs depend primarily on precipitation for their water source and are usually acidic and rich in plant residue with a conspicuous mat of living green moss

**boiler** a vessel designed to transfer heat produced by combustion or electric resistance to water. Boilers may provide hot water or steam

**boom** an elongate floating device (arm) used to contain oil on a body of water by physically blocking it for removal

**borehole** hole in the ground extending below the surface made with drilling equipment

**botanical pesticide** a pesticide whose active ingredient is a plant-produced chemical such as nicotine or strychnine. Also called a plant-derived pesticide

**bottom ash** the nonairborne combustion residue from burning pulverized coal in a boiler; the material that falls to the bottom of the boiler and is removed mechanically; a concentration of noncombustible materials, which may include toxic materials

**bounding estimate** an estimate of exposure, dose, or risk that is higher than that incurred by the person in the population with the currently highest exposure, dose, or risk. Bounding estimates are useful in developing statements that exposures, doses, or risks are not greater than an estimated value

**brackish water** a mix of freshwater and salt water such as that in an estuary

**breakthrough** a crack or break in a filter bed that allows the passage of floc or particulate mat-

ter through a filter. It can cause an increase in turbidity

**breathing zone** area of air in which an organism inhales

**breeder reactor** a fission reactor that generates more fissionable atoms, which are, in turn, consumed in subsequent reactions

**brine mud** waste material, often associated with well drilling or mining, composed of mineral salts or other inorganic compounds

**British thermal unit (BTU)** unit of heat energy equal to the amount of heat required to raise the temperature of one pound of water by one degree Fahrenheit at sea level

**broadcast application** the spreading of pesticides over an entire area rather than the individual applications where needed

**bubble** a system under which existing air emissions sources can propose alternate means to comply with a set of air emissions limitations. Under the bubble concept, sources can control more than required at one emission point where control costs are relatively low in return for a comparable relaxation of controls at a second emission point where control costs may be higher

**buffer** a solution or liquid whose chemical makeup is such that it minimizes changes in pH when acids or bases are added to it. Water can also be buffered to the chemistry of the surrounding rock or soil through chemical reactions that exchange ions in the water with those in the surrounding medium

**buffer strips** strips of grass or other erosion-resisting vegetation between or below cultivated strips or fields

**building cooling load** the hourly amount of heat that must be removed from a building to maintain indoor comfort (measured in British thermal units [BTUs])

**building envelope** the exterior surface of a building's construction: the walls, windows, floors, roof, and floor. Also called the building shell

**bulk sample** a small portion (usually thumbnail size) of a suspect asbestos-containing building material collected by an asbestos inspector for laboratory analysis to determine asbestos content. Also a sample of rock or soil that is representative of the chemistry of the entire body

**bulky waste** large items of waste materials, such as appliances, furniture, large auto parts, trees, stumps

**burial ground (graveyard)** a disposal site for radioactive waste materials that uses earth or water as a shield

**by-catch** the portion of a commercial fishing catch that consists of unintentionally caught species

**by-product** material, other than the principal product, generated as a consequence of an industrial process or as a breakdown product in a living system

**cap** a layer of clay or other impermeable material installed over the top of a closed landfill or encapsulated waste material to prevent entry of rainwater and minimize leachate

**capacity** the maximum quantity of sediment that a stream can carry

**capillary action** movement of water through very small spaces due to molecular forces called capillary forces

**capillary fringe** the porous material just above the water table that may hold water by capillarity (a property of surface tension that draws water upward) in the smaller void spaces. The zone above the water table within which the porous medium is saturated by water under less than atmospheric pressure

**carbon absorber** an add-on control device that uses activated carbon to absorb volatile organic compounds (VOCs) from a gas stream. The VOCs are later recovered from the carbon

**carbon adsorption** a treatment system that removes contaminants from groundwater or surface water by forcing it through tanks containing activated carbon treated to attract the contaminants

**carbon cycle** a nutrient and chemical exchange cycle consisting of the routes that carbon takes through the Earth's environmental systems

**carboxyhemoglobin** hemoglobin in which the iron is bound to carbon monoxide (CO) instead of oxygen

**carcinogen** any substance that can cause an increased incidence of cancer

**carrier** the inert liquid or solid material in a pesticide product that serves as a delivery vehicle for the active ingredient. Carriers do not have toxic properties of their own. Also, any material or system that can facilitate the movement of a pollutant into the body or cells

**carrying capacity** in recreation management, the amount of use a recreation area can sustain without loss of quality. In wildlife management, the maximal number of animals an area can support during a given period

**cask** a thick-walled container (usually lead) used to transport radioactive material. Also called a coffin

**CAS registration number** a number assigned by the Chemical Abstract Service to identify a chemical

**catalyst** a substance that changes the speed or yield of a chemical reaction or drives a chemical reaction without being consumed or chemically changed by the chemical reaction

**catalytic converter** an air pollution abatement device that removes pollutants from motor vehicle exhaust, by either oxidizing them into carbon dioxide and water or reducing them to nitrogen

**catalytic incinerator** a control device that oxidizes volatile organic compounds (VOCs) by using a catalyst to promote the combustion process. Catalytic incinerators require lower temperatures than conventional thermal incinerators, thus saving fuel and other costs

**categorical exclusion** a class of actions that either individually or cumulatively would not have a significant effect on the human environment and, therefore, would not require preparation of an Environmental Assessment (EA) or Environmental Impact Statement (EIS) under the National Environmental Policy Act (NEPA)

**categorical pretreatment standard** a technology-based wastewater limitation for an industrial facility discharging into a municipal sewer system. Analogous in stringency to Best Available Technology (BAT) for direct dischargers

**cathode** the positively charged electrode in a cell where reduction occurs

**cathodic protection** a technique to prevent corrosion of a metal surface by making it the cathode of an electrochemical cell

**cation** an ion that has a positive charge as the result of electron loss from the shell. It can be an element or compound

**cavitation** the formation and collapse of gas pockets or bubbles on the blade of an impellers, the gate of a valve, or in an ultrasonic cleaner; collapse of these pockets or bubbles drives water with such force that it can cause pitting of the gate or valve surface

**cells** in solid waste disposal, holes where waste is dumped, compacted, and covered with layers of dirt on a daily basis. In biology, the smallest structural part of living matter capable of functioning as an independent unit

**cementitious** densely packed and nonfibrous friable materials

**central collection point** location where a generator of regulated medical waste consolidates wastes originally generated at various locations in the facility. The wastes are gathered together for treatment on-site or for transportation elsewhere for treatment and/or disposal. This term

could also apply to community hazardous waste collections and industrial and other waste management systems

**centrifugal collector** a mechanical system using centrifugal force to remove aerosols from a gas stream or to remove water from sludge

**CERCLIS** the federal Comprehensive Environmental Response, Compensation, and Liability Information System, a database that includes all sites that have been nominated for investigation by the Superfund program and inclusion on the National Priorities List (NPL)

**chain of custody (COC)** documentation used to describe how environmental samples were managed from the time of collection through delivery to the laboratory and subsequent receipt of a written analytical report

**channelization** straightening and deepening streams so water will move faster. A marsh-drainage tactic that can interfere with waste assimilation capacity, disturb fish and wildlife habitats, and aggravate flooding

**characteristic** any one of the four categories used in defining hazardous waste; ignitability, corrosivity, reactivity, and toxicity

**characterization of ecological effects** part of ecological risk assessment that evaluates ability of an environmental stressor to cause adverse effects under given circumstances

**characterization of exposure** portion of an ecological risk assessment that evaluates interaction of a stressor with one or more ecological entities

**check-valve tubing pump** water sampling tool also referred to as a water pump

**chemical bond** the linkage between atoms by electron interactions in molecules and between molecules and ions in crystals

**chemical compound** a distinct and pure substance formed by the union of two or more elements in definite proportion by charge and atomic radius

**chemical element** a fundamental substance comprising a specific type of atom with characteristic atomic mass, charge, and radius; the simplest form of matter

**chemical oxygen demand (COD)** a measure of the oxygen required to oxidize all compounds, both organic and inorganic, in a given sample of water

**chemical stressors** chemicals released to the environment through industrial waste, auto emissions, pesticides, and other human activity that can cause illnesses and even death in plants and animals

**chemical treatment** any one of a variety of methods and technologies that use chemicals or a variety of chemical processes to treat waste

**chemosterilant** a chemical that controls pests by preventing reproduction

**chemosynthesis** a process in which an organism uses energy from reactions of certain chemicals and is not dependent upon photosynthesis

**chiller** a device that generates a cold liquid that is circulated through an air-handling unit's cooling coil to cool the air supplied to the building

**chilling effect** the lowering of the Earth's temperature because increased particles in the air block the Sun's rays

**chisel plowing** preparing croplands by using a special implement that avoids complete inversion of the soil, as in conventional plowing. Chisel plowing can leave a protective cover or crop residues on the soil surface to help prevent erosion and improve filtration

**chlorinated hydrocarbons** chemicals containing only chlorine, carbon, and hydrogen. These include a class of persistent, broad-spectrum insecticides that linger in the environment and accumulate in the food chain. Among them are DDT, aldrin, dieldrin, heptachlor, chlordane, lindane, endrin, Mirex, hexachloride, and toxaphene. Other examples include TCE, used as an industrial solvent. Also, any chlorinated organic compounds including chlorinated solvents such as dichloromethane, trichloromethylene, or chloroform

**chlorination** the application of chlorine to drinking water, sewage, or industrial waste to disinfect or to oxidize undesirable compounds

**chlorinator** a device that adds chlorine, in gas or liquid form, to water or sewage to kill infectious bacteria

**chlorine-contact chamber** that part of a water treatment plant where effluent wastewater is disinfected by chlorine

**chlorofluorocarbons (CFCs)** a family of inert, nontoxic, and easily liquefied chemicals used in refrigeration, air-conditioning, packaging, or insulation, or as solvents and aerosol propellants. CFCs are not destroyed in the lower atmosphere and can drift into the upper atmosphere, where their chlorine components destroy ozone. They are regulated under the Montreal Protocol

**chlorophenoxyl** a class of herbicides that may be found in domestic water supplies and cause adverse health effects

**chlorosis** discoloration of normally green plant parts caused by disease, lack of nutrients, or various air pollutants

**cholinesterase** an enzyme found in animals that regulates nerve impulses by the inhibition of acetylcholine. Cholinesterase inhibition is associated with a variety of acute symptoms, such as nausea, vomiting, blurred vision, stomach cramps, and rapid heart rate

**chromatography** an analytical technique that employs two materials, one moving and one stationary, to separate a mixture into its components. The form can be gas or liquid chromatography

**chronic effect** an adverse effect on a human or animal in which symptoms recur frequently or develop slowly over a long period

**chronic exposure** multiple exposures or continuous exposure to a substance over an extended period or over a significant fraction of an animal or human lifetime, usually seven years to a lifetime

**chronic toxicity** the capacity of a substance to cause long-term poisonous health effects in humans, animals, fish, and other organisms

**cistern** small tank or storage facility used to store water for a home or farm; often used to store rainwater

**clarification** clearing action that occurs during wastewater treatment when solids settle out. This is often aided by centrifugal action and chemically induced coagulation in wastewater

**clarifier** a tank in which solids settle to the bottom and are subsequently removed as sludge

**class I area** under the Clean Air Act, a class I area is one in which visibility is protected more stringently than under the National Ambient Air Quality Standards; includes national parks, wilderness areas, monuments, and other areas of special national and cultural significance

**class I substance** one of several groups of chemicals with an ozone depletion potential of 0.2 or higher, including CFCs, halons, carbon tetrachloride, and methyl chloroform (listed in the Clean Air Act) and HBFCs and ethyl bromide (added by EPA regulations)

**class II substance** a substance with an ozone depletion potential of less than 0.2. All HCFCs are currently included in this classification

**clean coal technology** any technology not in widespread use prior to the Clean Air Act Amendments of 1990. The use of clean coal technology is intended to achieve significant reductions in pollutants associated with the burning of coal

**clean fuels** blends or substitutes for gasoline fuels, including compressed natural gas, methanol, ethanol, and liquefied petroleum gas designed to reduce emission of air pollutants

**cleanup** actions taken to deal with a release or threat of release of a hazardous substance that could affect humans and/or the environment. The term *cleanup* is sometimes used interchangeably with the terms *remedial action*, *removal action*, *response action*, and *corrective action*

**clear-cut** harvesting all the trees in one area at one time, a practice that can encourage fast rainfall or snowmelt runoff, erosion, sedimentation of streams and lakes, and flooding and destroys vital habitat

**clear well** a reservoir for storing filtered water of sufficient quantity to eliminate the need to vary the filtration rate with variations in demand. Also used to provide chlorine contact time for disinfection

**climate** the composite pattern of long-term weather conditions that can be expected in a given region

**climate change** (also referred to as global climate change) the term *climate change* is sometimes used to refer to all forms of climatic inconsistency, but because the Earth's climate is never static, the term is more properly used to imply a significant change from one climatic condition to another. In some cases, *climate change* has been used synonymously with the term *global warming*; scientists, however, tend to use the term in the wider sense to include natural changes in climate

**cloning** in biotechnology, obtaining a group of genetically identical cells from a single cell; making identical copies of a gene

**closed-loop recycling** reclaiming or reusing wastewater for nonpotable purposes in an enclosed process

**closed system** a system (network of biotic and abiotic relationships) that is isolated and self-contained

**closure** the procedure an operator must follow when a landfill reaches its legal capacity for acceptance of solid waste

**coagulation** clumping of particles in wastewater to settle out impurities, often induced by chemicals such as lime, alum, and iron salts

**coal cleaning technology** a precombustion process by which coal is physically or chemically treated to remove some of its sulfur and reduce sulfur dioxide emissions

**coal gasification** conversion of coal to a gaseous product by one of several available technologies

**coastal zone** lands and waters adjacent to the coastline of a landmass that exert an influence on the uses of the sea and its ecology, or whose uses and ecology are affected by the sea

**Code of Federal Regulations (CFR)** document that codifies all rules of the executive departments and agencies of the federal government. It is divided into 50 volumes, known as titles. Title 40 of the CFR (referenced as 40 CFR) lists all environmental regulations

**Coefficient of Haze (COH)** a measurement of visibility interference in the atmosphere

**cofire** burning of two fuels in the same combustion unit (e.g., coal and natural gas, or oil and coal)

**cogeneration** the consecutive generation of useful thermal and electric energy from the same fuel source

**coke** the solid residue of impure carbon obtained from bituminous coal and other carbonaceous materials after removal of volatile material by destructive distillation. It is used as a fuel and in making steel

**coke oven** an industrial oven that converts coal into coke, one of the basic materials used in blast furnaces for the conversion of iron ore into iron

**cold temperature CO** a standard for automobile emissions of carbon monoxide (CO) emissions to be met at a low temperature (i.e., 20°F Fahrenheit). Conventional automobile catalytic converters are not efficient in cold weather until they warm up

**Coliform Index** a rating of the purity of water based on a count of fecal bacteria

**coliform organism** microorganism found in the intestinal tract of humans and animals. Its presence in water indicates fecal pollution and potentially adverse contamination by pathogens

**collector** public or private hauler that collects nonhazardous waste and recyclable materials from residential, commercial, institutional, and industrial sources

**collector sewers** pipes used to collect and carry wastewater from individual sources to an interceptor sewer that will carry it to a treatment facility

**colloids** very small, finely disseminated solids (that do not dissolve) that remain dispersed in a liquid for a long time because of their small size and electrical charge

**combined sewer overflows** discharge of a mixture of storm water and domestic waste when the flow capacity of a sewer system is exceeded during rainstorms or other floods

**combined sewers** a sewer system that carries both sewage and storm-water runoff. Normally, its entire flow goes to a waste treatment plant, but during a heavy storm or thaw, the volume of water may cause overflow of untreated mixtures of storm water and sewage into receiving

waters. Storm-water runoff may also carry toxic chemicals from industrial areas or streets into the sewer system

**combustion** burning, or rapid oxidation, accompanied by release of energy in the form of heat and light. Also refers to controlled burning of waste, in which heat chemically alters organic compounds, converting them into stable inorganic compounds such as carbon dioxide and water

**combustion chamber** the actual compartment where waste is burned in an incinerator

**combustion product** substance produced during the burning or oxidation of a material

**command-and-control regulations** specific requirements prescribing how to comply with specific standards defining acceptable levels of pollution

**commensalism** a relationship between species in which one organism benefits and the other is unaffected (e.g., one plant living on the surface of another)

**comment period** time provided for the public to review and comment on a proposed EPA action or rule making after publication in the Federal Register

**commercial waste** all solid waste emanating from business establishments such as stores, markets, office buildings, restaurants, shopping centers, and theaters

**commercial waste management facility** a treatment, storage, disposal, or transfer facility that accepts waste from a variety of sources, as compared to a private facility, which normally manages a limited waste stream generated by its own operations

**comminuter** a machine that shreds or pulverizes solids to make waste treatment easier

**comminution** mechanical shredding or pulverizing of waste. Used in both solid waste management and wastewater treatment

**commonsense initiative** voluntary program to simplify environmental regulation to achieve cleaner, cheaper, smarter results, starting with six major industry sectors

**community** in ecology, an assemblage of populations of different species within a specified location in space and time. Sometimes, a particular subgrouping may be specified, such as the fish community in a lake or the soil arthropod community in a forest

**community relations** the EPA effort to establish two-way communication with the public to create understanding of EPA programs and related actions, to ensure public input into decision-

making processes related to affected communities, and to make certain that the agency is aware of and responsive to public concerns. Specific community relations activities are required in relation to Superfund remedial actions

**community water system** a public water system that has at least 15 service connections used by year-round residents or regularly serves at least 25 year-round residents

**compact fluorescent lamp (CFL)** small fluorescent lamp used as more efficient alternative to incandescent lighting. Also called PL, CFL, Twin-Tube, or BIA-X lamps

**compaction** reduction of the bulk of solid waste by rolling and tamping

**comparative risk assessment** a process that generally uses the judgment of experts to predict effects and set priorities among a wide range of environmental problems

**competence** a measure of the largest particles that a stream can transport

**compliance coal** any coal that emits less than 1.2 pounds of sulfur dioxide per million BTU when burned. Also known as low-sulfur coal

**compliance monitoring** collection and evaluation of data, including self-monitoring reports, and verification to show whether pollutant concentrations and loads contained in permitted discharges are in compliance with the limits and conditions specified in the permit

**compliance schedule** a negotiated agreement between a pollution source and a government agency that specifies dates and procedures by which a source will reduce emissions and, thereby, comply with a regulation

**composite sample** a series of water samples taken over a given period and weighted by flow rate

**composting** the controlled biological decomposition of organic material in the presence of air to form a humus-like material. Controlled methods of composting include mechanical mixing and aerating, ventilating the materials by dropping them through a vertical series of aerated chambers, or placing the compost in piles out in the open air and mixing it or turning it periodically

**composting facilities** an off-site facility where the organic component of municipal solid waste is decomposed under controlled conditions. Also, an aerobic process in which organic materials are ground or shredded and then decomposed to humus in windrow piles (long rows) or in mechanical digesters, drums, or similar enclosures

**compound** a substance that can be decomposed into its elements by chemical processes

**concentration** the relative amount of a substance mixed with another substance. An example is five parts per million of carbon monoxide in air or 1 mg/L of iron in water

**condensate** water created by cooling steam or water vapor

**condensation** the conversion of a gas into a liquid

**conditionally exempt generators (CE)** persons or enterprises that produce less than 220 pounds (100 kg) of hazardous waste per month. Exempt from most regulation, they are required merely to determine whether their waste is hazardous, notify appropriate state or local agencies, and ship it by an authorized transporter to a permitted facility for proper disposal

**conductance** a rapid method of estimating the dissolved solids content of water supply by determining the capacity of a water sample to carry an electrical current. Conductivity is a measure of the ability of a solution to carry an electrical current

**conduction** the transport of heat by atomic or molecular motion

**conductivity** a measure of the ability of a solution to carry an electrical current

**cone of depression** a depression or lowering in the water table in an inverted cone shape that develops around a pumping well

**cone penetrometer testing (CPT)** a direct push system used to measure lithology based on soil penetration resistance. Sensors in the tip of the cone of the direct push rod measure tip resistance and sidewall friction, transmitting electrical signals to digital processing equipment on the ground surface

**confidential business information (CBI)** material that contains trade secrets or commercial or financial information that has been claimed as confidential by its source (e.g., a pesticide or new chemical formulation registrant). The EPA has special procedures for handling such information

**consent decree** a legal document, approved by a judge, that formalizes an agreement reached between EPA and potentially responsible parties (PRPs) of a Superfund site through which PRPs will conduct all or part of a cleanup action, to cease or correct actions or processes that are polluting the environment, or otherwise comply with EPA-initiated regulatory enforcement actions to resolve the contamination at the Superfund site involved. The consent decree

describes the actions PRPs will take and may be subject to a public comment period

**conservation** preserving and renewing, when possible, human and natural resources. The use, protection, and improvement of natural resources according to principles that will ensure their highest economic or social benefits

**conservation easement** an easement restricting or limiting a landowner to land uses that are compatible with long-term conservation and environmental values

**constituent(s) of concern** specific chemical identified for evaluation in the site assessment process

**construction and demolition waste** waste building materials, dredging materials, tree stumps, and rubble resulting from construction, remodeling, repair, and demolition of homes, commercial buildings, and other structures and pavements. May contain lead, asbestos, or other hazardous substances

**construction ban** if, under the Clean Air Act, the EPA disapproves an area's planning requirements for correcting nonattainment, the EPA can ban the construction or modification of any major stationary source of the pollutant for which the area is in nonattainment

**consumptive water use** water removed from available supplies without return to a water resources system (e.g., water used in manufacturing, agriculture, and food preparation)

**contact pesticide** a chemical that kills pests when it touches them, instead of by ingestion

**contaminant** any physical, chemical, biological, or radiological substance or matter that has an adverse effect on air, water, or soil

**contamination** introduction into water, air, and soil of microorganisms, chemicals, toxic substances, wastes, or wastewater in a concentration that makes the medium unfit for its current or intended use. Also applies to surfaces of objects, buildings, and various household and agricultural products

**continental margin** the region between the shoreline of a continent and the deep ocean basins including the continental shelf, continental slope, and continental rise

**continental rise** an apron of sediment between the continental slope and the deep seafloor that is shallower in slope than the continental slope but steeper than the abyssal plain

**continental slope** the relatively steep underwater slope between the continental shelf and the continental rise

- contingency plan** a document setting out an organized, planned, and coordinated course of action to be followed in case of a fire, explosion, or other accident that releases toxic chemicals, hazardous waste, or radioactive materials that threaten human health or the environment
- continuous discharge** a routine release to the environment that occurs without interruption, except for infrequent shutdowns for maintenance, process changes, etc.
- contour plowing** soil tilling method that follows the shape of the land to minimize erosion
- contour strip farming** a type of contour farming in which row crops are planted in strips, between alternating strips of close-growing, erosion-resistant forage crops
- contract labs** laboratories under contract to the EPA, that analyze samples taken from waste, soil, air, and water or carry out research projects
- controlled reaction** a chemical reaction under temperature and pressure conditions maintained within safe limits to produce a desired product or process
- control rod** a column of neutron-absorbing alloys that are spaced among fuel rods to manage (control) nuclear fission reactions
- convection** the transport of heat by the movement of thermally driven density currents in air, water, or liquid
- conventional pollutants** statutorily listed pollutants understood well by scientists. These may be in the form of organic waste, sediment, acid, bacteria, viruses, nutrients, oil and grease, or heat
- conventional tilling** tillage operations considered standard for a specific location and crop and that tend to bury the crop residues; usually considered as a base for determining the cost-effectiveness of control practices
- conveyance loss** water loss in pipes, channels, conduits, or ditches by leakage or evaporation
- cooling tower** a device that dissipates the heat from water-cooled systems by spraying the water through streams of rapidly moving air
- Copenhagen Accord** a 2009 international agreement to reduce carbon emissions by 2020
- core** the uranium-containing center of a nuclear reactor, where energy is released
- corrective action** the EPA can require treatment, storage, and disposal facilities (TSDF) that handle hazardous waste to undertake corrective actions to clean up spills resulting from failure to follow hazardous waste management procedures or other mistakes
- corrosion** the alteration and dissolution of a metal surface caused by a chemical reaction such as between water and pipes, chemicals touching a metal surface, or contact between two metals
- corrosive** a chemical agent (acid) that reacts with the surface of a material, causing it to deteriorate
- cost/benefit analysis** a quantitative evaluation of the costs that would have been incurred by implementing an environmental regulation versus the overall benefits to society of the proposed action
- cost-effective alternative** an alternative control or corrective method identified after analysis as being the best available in terms of reliability, performance, and cost. Although costs are one important consideration, regulatory and compliance analysis does not require EPA to choose the least expensive alternative. For example, when selecting or approving a method for cleaning up a Superfund site, EPA balances costs with the long-term effectiveness of the methods proposed and the potential danger posed by the site
- cost recovery** a legal process by which potentially responsible parties who contributed to contamination at a Superfund site can be required to reimburse the trust fund for money spent during any cleanup actions by the federal government
- cost sharing** a publicly financed program through which society, as a beneficiary of environmental protection, shares part of the cost of pollution control with those who must actually install the controls. In Superfund, for example, the government may pay part of the cost of a cleanup action and those responsible for the pollution pay the major share
- covalent bond** the bond that arises from atoms sharing electrons
- cover crop** a crop that provides temporary protection for delicate seedlings and/or provides a cover canopy for seasonal soil protection and nourishment between normal crop production periods
- cover material** soil used to cover compacted solid waste in a sanitary landfill
- cradle-to-grave or manifest system** a procedure in which hazardous materials are identified and tracked as they are produced, treated, transported, and disposed of by a series of permanent, linkable, descriptive documents (e.g., manifests). Commonly referred to as the cradle-to-grave system
- criteria** descriptive factors taken into account by EPA in setting standards for various pollutants. These factors are used to determine limits on allowable concentration levels and to limit the number of violations per year. When issued by EPA, the criteria provide guidance to the states on how to establish their standards

**criteria pollutants** the 1970 amendments to the Clean Air Act required the EPA to set National Ambient Air Quality Standards (NAAQS) for certain pollutants known to be hazardous to human health. The EPA identified and set standards to protect human health and welfare for six pollutants: ozone, carbon monoxide, total suspended particulates, sulfur dioxide, lead, and nitrogen oxide. The term *criteria pollutants* derives from the requirement that EPA describes the characteristics and potential health and welfare effects of these pollutants. It is on the basis of these criteria that standards are set or revised

**critical effect** the first adverse effect, or its known precursor, that occurs as a dose rate increases. Designation is based on evaluation of overall database

**critical mass** the minimal mass of fissionable material needed for a chain nuclear reaction to be self-sustained (e.g., one neutron formed by a fission is used to induce a second fission)

**crop rotation** planting a succession of different crops on the same land, as opposed to planting the same crop every season

**cross-connection** any actual or potential connection between a drinking water system and a water supply that is not approved for public consumption (i.e., sanitary sewer pipe) or other source of contamination

**cross-contamination** the movement of underground contaminants from one level or area to another due to invasive subsurface activities

**crude oil** the oil that is taken directly out of the ground is an unrefined mixture of hundreds of different hydrocarbons formed by the conversion of organic compounds by using heat and pressure. A fossil fuel

**crumb rubber** ground rubber fragments the size of sand or silt used in rubber or plastic products, or processed further into reclaimed rubber or asphalt products

**cubic feet per minute (CFM)** a measure of the volume of a substance flowing through air within a fixed period. With regard to indoor air, it refers to the amount of air that is exchanged with outdoor air in a minute's time (i.e., the air exchange rate)

**cullet** crushed glass

**cultures and stocks** infectious agents and associated biologicals including cultures from medical and pathological laboratories, agents from research and industrial laboratories, waste from the production of biologicals, discarded live and attenuated vaccines, and culture dishes

and devices used to transfer, inoculate, and mix cultures

**cumulative ecological risk assessment** consideration of the total ecological risk from multiple stressors to a given ecozone

**cumulative exposure** the sum of exposures of an organism to a pollutant over a period

**cuttings** piles of waste rock and/or sediment removed through the progressive drilling of a conventional well with hollow-stem auger or rotary drilling equipment that were returned to the surface to clear the well bore. Mainly associated with oil and gas wells

**cyclone collector** a spinning device that is cylindrical on top and conical on the bottom and uses centrifugal force to remove large particles from polluted air by forcing them to the walls of the cylinder before allowing them to settle to a collector in the bottom of the cone

**data quality objectives (DQOs)** qualitative and quantitative statements of the overall level of uncertainty that a decision maker will accept in results or decisions based on environmental data. They provide the statistical framework for planning and managing environmental data operations consistently with the user's need

**deadmen** anchors drilled or cemented into the ground to provide additional reactive mass for direct push sampling rigs

**decant** to draw off the upper layer of liquid after the heaviest material (a solid or another liquid) has settled

**decay products** the by-products of the decay of radioactive materials, often referred to as "daughters" or "progeny." The radon 222 decay products of most concern from a public health standpoint are polonium 214 and polonium 218

**dechlorination** removal of chlorine from a substance

**decomposer** an organism such as a fungus or bacterium that degrades nonliving matter into simpler constituents that can then be utilized by plants

**decomposition** the breakdown of matter by bacteria and fungi, changing the chemical makeup and physical appearance of materials

**decontamination** removal of harmful substances such as noxious chemicals, disease-causing bacteria or other organisms, or radioactive material from exposed individuals, rooms, and furnishings in buildings or the exterior environment

**deep-well injection** deposition of raw or treated, filtered hazardous waste by pumping it into wells that are much deeper than any public water supply, where it is contained in the pores of permeable subsurface rock

**deflocculating agent** a material added to a suspension to prevent settling

**defluoridation** the removal of excess fluoride in drinking water to prevent the staining of teeth

**defoliant** an herbicide that removes leaves from trees and growing plants

**deforestation** the clearing and permanent loss of forest and forest-related ecosystems. Done primarily for agriculture but also development

**degasification** a water treatment that removes dissolved gases from the water

**degree-day** a rough measure used to estimate the amount of heating required in a given area. It is defined as the difference between the average (mean) daily temperature and 65°F (18.3°C). Degree-days also are calculated to estimate cooling requirements

**delist** use of the petition process to have a facility's toxic designation rescinded

**demand-side waste management** prices whereby consumers use purchasing decisions to communicate to product manufacturers that they prefer environmentally sound products packaged with the least amount of waste, made from recycled or recyclable materials, and containing no hazardous substances

**demineralization** a treatment process that removes dissolved minerals from water

**denitrification** the biological reduction of nitrate to nitrogen gas by denitrifying bacteria in soil

**density** a measure of mass per unit volume of material or how massive a specific volume of a solid, liquid, or gas is in comparison to the same volume of water

**depressurization** a condition that occurs when the air pressure inside a structure is lower than the air pressure outdoors. Depressurization can occur when household appliances such as fireplaces or furnaces, which consume or exhaust house air, are not supplied with enough makeup air. Radon may be drawn into a house more rapidly under depressurized conditions

**dermal absorption or penetration** process by which a chemical penetrates the skin and enters the body as an internal dose

**dermal toxicity** the ability of a pesticide or toxic chemical to poison people or animals by contact with the skin

**DES** a synthetic estrogen, diethylstilbestrol. It is used as a growth stimulant in food animals. Residues in meat are thought to be carcinogenic

**desalination** removal of salts from ocean or brackish water. Also, removal of salts from soil by artificial means, usually leaching

**desiccant** a chemical agent that absorbs moisture and dries materials. Some desiccants are capable of drying out plants or insects, causing death

**designated pollutant** an air pollutant that is neither a criteria nor hazardous pollutant, as described in the Clean Air Act, but for which new source performance standards exist. The Clean Air Act does require states to control these pollutants, such as acid mist, total reduced sulfur (TRS), and fluorides

**designated uses** those water uses identified in state water quality standards that must be achieved and maintained as required under the Clean Water Act. Uses can include cold water fisheries, public water supply, and irrigation

**design capacity** the average daily flow of liquid or air that a treatment plant or other facility is designed to accommodate

**designer bugs** popular term for microbes developed through biotechnology (genetic engineering) that can degrade specific toxic chemicals of interest at their source in toxic waste dumps or in groundwater

**destination facility** the facility to which regulated medical waste is shipped for treatment and destruction, incineration, and/or disposal

**destratification** vertical mixing within a lake or reservoir to eliminate separate layers of temperature, plant, or animal life totally or partially

**destroyed medical waste** regulated medical waste that has been ruined, torn apart, or mutilated through thermal treatment, melting, shredding, grinding, tearing, or breaking, so that it is no longer generally recognized as medical waste but has not yet been treated (excludes compacted regulated medical waste)

**destruction and removal efficiency (DRE)** a percentage that represents the number of molecules of a compound removed or destroyed in an incinerator relative to the number of molecules entering the system (e.g., a DRE of 99.99 percent means that 9,999 molecules are destroyed for every 10,000 that enter; 99.99 percent is known as four nines. For some pollutants, the removal requirement may be as stringent as "six nines")

**destruction facility** a facility that destroys regulated medical waste

**desulfurization** removal of sulfur from fossil fuels to reduce pollution

**detectable leak rate** the smallest leak from a storage tank, expressed in terms of gallons or liters per hour, that a test can reliably discern with a certain probability of detection or false alarm

- detection criterion** a predetermined rule to ascertain whether a tank is leaking or not. Most volumetric tests use a threshold value (0.05 gallon per hour) as the detection criterion
- detection limit** the lowest concentration of a chemical that can reliably be distinguished from a zero concentration
- detention time** the theoretical calculated time required for a small amount of water to pass through a tank at a given rate of flow. Also, the actual time that a small amount of water is in a settling basin, flocculating basin, or rapid-mix chamber. In storage reservoirs, it is the length of time water will be held before being used
- detritivore** an organism that consumes the waste products or dead bodies of other organisms
- development effects** adverse effects such as altered growth, structural abnormality, or functional deficiency observed in a developing organism
- dewater** removal or separation of a portion of the water in a sludge or slurry to dry the sludge so it can be handled and disposed of. Also, to remove or drain water from a tank or trench
- diatomaceous earth (diatomite)** a chalklike material (fossilized diatoms) used to filter out solid waste in wastewater treatment plants. Also used as an active ingredient in some powdered pesticides
- dicofol** a pesticide used on citrus fruits
- diffused air** a type of aeration process that forces oxygen into sewage by pumping air through perforated pipes inside a holding tank
- diffusion** the movement of suspended or dissolved particles (or molecules) from an area of higher concentration to an area of lower concentration. The process tends to distribute the particles or molecules more uniformly
- digester** in wastewater treatment, a closed tank. In solid-waste conversion, a unit in which bacterial action is induced and accelerated in order to break down organic matter and establish the proper carbon-to-nitrogen ratio
- digestion** the biochemical decomposition of organic matter, resulting in partial gasification, liquefaction, and mineralization of pollutants
- dike** a low wall that can act as a barrier to prevent a spill from spreading. A trench cut into the surface. In geology, a sheetlike intrusive igneous rock that cuts across the strata of the surrounding rock
- dilutents** any liquid or solid material used to dilute or carry an active ingredient
- dilution ratio** the fraction or percentage of the volume of water in a stream versus the volume of incoming water. It affects the ability of the stream to assimilate waste
- dimictic** lakes and reservoirs that freeze over and normally go through two stratifications and two mixing cycles a year
- dinocap** a fungicide used primarily by apple growers to control summer diseases. EPA proposed restrictions on its use in 1986 when laboratory tests found it caused birth defects in rabbits
- dinoseb** a herbicide that is also used as a fungicide and insecticide. It was banned by EPA in 1986 because it posed the risk of birth defects and sterility
- direct discharger** a municipal or industrial facility that introduces pollution through a defined conveyance or system such as outlet pipes
- direct filtration** a method of treating water that consists of the addition of coagulant chemicals, flash mixing, coagulation, minimal flocculation, and filtration
- direct push** technology used for performing subsurface investigations by driving, pushing, and/or vibrating small-diameter hollow steel rods into the ground. Also known as direct drive, drive point, or push technology
- direct runoff** water that flows over the ground surface directly into streams, rivers, and lakes
- discharge** the quantity of fluid or gas past a specific point equal to velocity multiplied by the cross-sectional area through which it flows. Flow of surface water in a stream or canal or the outflow of groundwater from a flowing artesian well, ditch, or spring. The term can also apply to discharge of liquid-treated wastewater from a facility or to chemical emissions into the air through designated venting mechanisms
- disinfectant** a chemical or physical process that kills pathogenic organisms in water, in air, or on surfaces. Chlorine often is used to disinfect sewage treatment effluent, water supplies, wells, and swimming pools
- disinfectant by-product** a compound formed by the reaction of a disinfectant such as chlorine with organic material in the water supply. Also, a chemical by-product of the disinfection process
- disinfectant time** the time it takes water to move from the point of disinfectant application (or the previous point of residual disinfectant measurement) to a point before or at the point where the residual disinfectant is measured. In pipelines, the time is calculated by dividing the internal volume of the pipe by the maximal hourly flow rate. Within mixing basins and storage reservoirs, it is determined by tracer studies or an equivalent demonstration

**dispersant** a chemical agent used to break up concentrations of organic material such as spilled oil so that it can be further chemically or biologically degraded

**disposal** final placement or destruction of toxic, radioactive, or other wastes; surplus or banned pesticides or other chemicals; polluted soils; and drums containing hazardous materials from removal actions or accidental releases. Disposal may be accomplished through use of approved secure landfills, surface impoundments, land farming, deep-well injection, ocean dumping, or incineration

**disposal facilities** repositories for solid waste, including landfills and combustors intended for permanent containment or destruction of waste materials. Excludes transfer stations and composting facilities

**disseminated ore deposit** a large, low-grade ore deposit in which generally fine-grained metal-bearing minerals are widely scattered throughout a rock body is sufficient concentration to make the deposit economical to mine

**dissolved load** the portion of a stream's sediment load that is carried in solution

**dissolved oxygen (DO)** the available oxygen in water, vital to fish and other aquatic life and for the prevention of odors. DO levels are considered an important indicator of a water body's ability to support desirable aquatic life. Secondary and advanced waste treatments are generally designed to ensure adequate DO in waste-receiving waters

**dissolved solids** disintegrated organic and inorganic material in water. Excessive amounts make water unfit to drink or use in industrial processes

**distillation** the act of purifying liquids through boiling, so that the steam or gaseous vapors condense to a pure liquid. Pollutants and contaminants may remain in the concentrated, undistilled residue

**disturbance** any event or series of events that disrupt ecosystem, community, or population structure and alter the physical environment

**diversion** use of part of a stream as a water supply. Also, a channel with a supporting ridge on the lower side constructed across a slope to divert water at a nonerosive velocity to sites where it can be used and disposed of

**diversion rate** the percentage of waste materials diverted from traditional disposal such as land-filling or incineration to be recycled, composted, or reused

**DNA (deoxyribonucleic acid)** a large organic molecule inside the chromosomes of the cell that stores genetic information. Responsible for passing biological traits from parents to offspring

**DNA hybridization** use of a segment of DNA, called a DNA probe, to identify its complementary DNA; used to detect specific genes

**DNAPL (dense nonaqueous phase liquid)** non-aqueous phase liquids such as chlorinated hydrocarbon solvents or petroleum fractions with a specific gravity greater than 1.0 sink through the water column until they reach a confining layer. They settle at the bottom of aquifers instead of floating on the water table, and typical monitoring wells do not indicate their presence. Cleanup of DNAPL is much more difficult

**Dobson unit (DU)** units of ozone level measurement. If, for example, 100 DU of ozone were taken to the Earth's surface, it would form a layer 0.04 inch (1 mm) thick

**domestic application** pesticide application in and around houses, office buildings, motels, and other living or working areas

**dosage/dose** the actual quantity of a chemical administered to an organism or to which it is exposed. Also, the amount of a substance that reaches a specific tissue (e.g., the liver). It also can mean the amount of a substance available for interaction with metabolic processes after crossing the outer boundary of an organism

**dose equivalent** the measure of an absorbed dose of ionizing radiation in an organism that accounts for biological differences, the type of radiation, and its distribution in the body

**dose rate** in exposure assessment, dose per time unit (e.g., mg/day). Also called dosage

**dose-response assessment** the estimate of the potency of a chemical. In exposure assessment, the process of determining the relationship between the dose of a stressor and a specific biological response. Also, evaluating the quantitative relationship between dose and toxicological responses

**dose-response curve** graphical representation of the relationship between the dose of an environmental stressor and the associated biological response (e.g., number of cigarettes smoked and the incidence of lung cancer)

**dose-response relationship** the quantitative relationship between the amount of exposure to a substance and the extent of toxic injury or disease it produces

**dosimeter** an instrument to measure dosage. Many so-called dosimeters actually measure exposure rather than dosage. Dosimetry is the

process or technology of measuring and/or estimating dosage

**DOT reportable quantity** the quantity of a hazardous or dangerous substance specified in a U.S. Department of Transportation regulation that triggers labeling, packaging, and other requirements related to shipping such substances

**downgradient** the direction that groundwater flows. Similar to *downstream* for surface water

**DP hole** hole in the ground made with direct push (DP) equipment

**draft permit** a preliminary permit drafted and published by EPA. It is subject to public review and comment before final action on the application

**drainage** improving the productivity of agricultural land by removing excess water from the soil by such means as ditches or subsurface drainage tiles

**drainage basin** the area of land that drains surface water, groundwater, sediment, and dissolved materials to a common stream channel

**drainage well** a well drilled to carry excess water off agricultural fields. Drainage wells act as a funnel from the surface to the groundwater below, where they can contribute to groundwater pollution

**drawdown** the drop in the water table or level of water in the ground when water is being pumped from a well. The amount of water used from a tank or reservoir. It also refers to the drop in the water level of a tank or reservoir

**dredging** removal of mud, silt, and other materials from the bottom of water bodies. This can disturb the ecosystem and cause increased turbidity that destroys aquatic life. Dredging of contaminated materials can expose biota to heavy metals and other toxics. Dredging activities may be subject to regulation under Section 404 of the Clean Water Act

**drilling fluid** fluid used to lubricate the bit and convey drill cuttings to the surface with rotary drilling equipment. Usually composed of bentonite slurry or muddy water. Can become contaminated and may require special disposal

**drinking water equivalent level** protective level of exposure related to potentially noncarcinogenic effects of chemicals that are also known to cause cancer

**drinking water state revolving fund** the fund provides capitalization grants to states to develop drinking water revolving loan funds to help finance system infrastructure improvements, assure source-water protection, enhance

operation and management of drinking-water systems, and otherwise promote local water-system compliance and protection of public health

**drive casing** heavy-duty steel casing driven along with the sampling tool in cased direct push (DP) systems. Keeps the borehole open between sampling tool runs and is not removed until last sample has been collected

**drop-off** recyclable materials collection method in which individuals take them to a designated collection site

**dual-phase extraction** active withdrawal of both liquid and gas phases from a well, usually involving the use of a vacuum pump

**dump** a site used to dispose of solid waste without environmental controls

**duplicate** a second sample that is treated the same way as the original sample in order to determine the precision of the analytical method

**dustfall jar** an open container used to collect large particles from the air for measurement and analysis

**dynamometer** a device used to place a load on an engine and measure its performance

**dystrophic lakes** acidic, shallow bodies of water that contain much humus and/or other organic matter; contain many plants but few fish

**Earth Day** an annual worldwide celebration in April showing support for environmental protection

**ecological entity** in ecological risk assessment, a general term referring to a species, a group of species, an ecosystem function or characteristic, or a specific habitat or biome

**ecological exposure** exposure of a nonhuman organism to a stressor

**ecological impact** the effect of an artificial or natural activity on living organisms and their nonliving (abiotic) environment

**ecological indicator** a biotic or abiotic characteristic of an ecosystem that can be measured and that directly reflects integrity and sustainability of the system

**ecological integrity** a living system exhibits its integrity if, when subjected to disturbance, it corrects itself to a sustainable biomass end state. End states other than that which occurs in nature may be satisfactory

**ecological risk assessment** the assessment of the effects of human actions on a natural resource and the significance of those effects. Such analysis includes initial hazard identification, exposure and dose-response assessments, and risk characterization

**ecological sustainability or environmental sustainability** maintenance of ecosystem components and functions for future generations

**ecology** the relationship of living things to each other and their environment, or the study of such relationships

**economic poisons** chemicals used to control pests and to defoliate cash crops such as cotton

**ecosphere** the “biobubble” that contains life on Earth, in surface waters, and in the air

**ecosystem** the interacting system of a biological community and its nonliving environmental surroundings

**ecosystem structure** the relationship of the attributes of an ecosystem such as species population density, species richness or distribution, and standing crop biomass

**ecotone** a habitat created by the juxtaposition of distinctly different habitats; an edge habitat; or an ecological zone or boundary where two or more ecosystems meet

**effluent** wastewater—treated or untreated—that flows out of a treatment plant, sewer, or industrial outfall (pipe). Generally refers to wastes discharged into surface waters

**effluent guidelines** technical EPA documents that set effluent limitations for given industries and pollutants

**effluent limitation** restrictions established by a state or the EPA on quantities, rates, and concentrations of contaminants in wastewater discharges

**effusion** the passage of a gas through a small hole into an evacuated space

**ejector** a device used to disperse a chemical solution into water being treated

**electrochemistry** the study of the relationship between chemical reactions and electrical charges

**electrodialysis** a process that uses electrical current applied to permeable membranes to remove minerals from water. Often used to desalinate salty or brackish water

**electrolyte** a substance that separates into ions when it dissolves in water

**electromagnetic spectrum** the entire range of electromagnetic radiation from very long-wavelength, low-frequency radiation to very short-wavelength, high-frequency radiation. It includes X-rays, ultraviolet radiation, visible light, and infrared radiation, among others

**electron capture** a mode of radioactive decay for some unstable nuclides in which the nucleus captures an electron and converts a proton into a neutron. It can be used as an analytical tool or

an add-on to improve precision, especially with a gas chromatograph (GC)

**electroplating** the electrolytic deposition of a thin, uniform metal film on the surface of an object

**electrostatic precipitator (ESP)** a device that removes particles from a gas stream (smoke) after combustion occurs. The ESP imparts an electrical charge to the particles, causing them to adhere to metal plates inside the precipitator. Rapping on the plates causes the particles to fall into a hopper for disposal

**element** the basic form of a chemical species uniquely defined by its nuclear and electron configuration

**emergency (chemical)** a situation created by an accidental release or spill of hazardous chemicals that poses a threat to the safety of workers, residents, the environment, or property

**emergency and hazardous chemical inventory** a mandatory annual report that must be prepared by facilities having one or more extremely hazardous substances or hazardous chemicals above certain weight limits

**emergency exemption** provision in FIFRA under which EPA can grant temporary exemption to a state or another federal agency to allow the use of a pesticide product not registered for that particular use. Such actions involve unanticipated and/or severe pest problems where there is not time or interest by a manufacturer to register the product for that use

**emergency removal action** steps taken to remove contaminated materials that pose an imminent threat to local residents (e.g., removal of leaking drums or excavation of explosive waste)

**emergency response values** concentrations of chemicals, published by various scientific and governmental groups, defining acceptable levels for short-term exposures in emergencies

**emergency suspension** suspension of a pesticide product registration due to an imminent hazard. The action immediately halts distribution, sale, and sometimes actual use of the pesticide involved

**emergent coastline** a coastline that recently was underwater but has now been exposed because the land has risen or sea level has fallen

**emission** pollution discharged into the atmosphere from smokestacks, other vents, and surface areas of commercial or industrial facilities; from residential chimneys; and from motor vehicle, locomotive, or aircraft exhausts

**emission cap** a limit designed to prevent projected growth in emissions from existing and future stationary sources that erode any mandated reductions. Generally, such provisions require that any emission growth from facilities under the restrictions must be offset by equivalent reductions at other facilities under the same cap

**emission factor** the relationship between the amount of pollution produced and the amount of raw material processed. For example, an emission factor for a blast furnace making iron would be the number of pounds (kilograms) of particulates per ton (metric ton) of raw materials

**emission inventory** a listing, by source, of the amount of air pollutants discharged into the atmosphere of a community. Used to establish emission standards

**emission standard** the maximal amount of air polluting discharge legally allowed from a single source, mobile or stationary

**emissions trading** the creation of surplus emission reductions at certain stacks, vents, or similar emission sources and the use of this surplus to meet or redefine pollution requirements applicable to other emissions sources. This allows one source to increase emissions when another source reduces them, maintaining an overall constant emission level. Facilities that reduce emissions substantially may “bank” their “credits” or sell them to other facilities or industries

**emulsifier** a chemical that aids in suspending one liquid in another. Usually an organic chemical in an aqueous solution

**encapsulation** the treatment of asbestos-containing material with a liquid that covers the surface with a protective coating or embeds fibers in an adhesive matrix to prevent their release into the air

**enclosure** the installation of an airtight, impermeable, permanent barrier around asbestos-containing materials to prevent the release of asbestos fibers into the air

**endangered species** animals, birds, fish, plants, or other living organisms threatened with extinction by human activities or other natural changes in their environment. Requirements for declaring a species endangered are contained in the Endangered Species Act

**endangerment assessment** a study to determine the nature and extent of contamination at a site on the National Priorities List and the risks posed to public health or the environment. The EPA or the state conducts the study when a legal

action is to be taken to direct potentially responsible parties (PRPs) to clean up a site or pay for such a cleanup. An endangerment assessment supplements a remedial investigation

**end-of-the-pipe** technologies such as scrubbers on smokestacks and catalytic converters on automobile tailpipes that reduce emissions of pollutants after they have formed

**endothermic reaction** a reaction that absorbs heat from the surroundings

**end-use product** a pesticide formulation for field or other end use. The label has instructions for use or application to control pests or regulate plant growth. The term excludes products used to formulate other pesticide products

**energy recovery** obtaining energy from waste through a variety of processes (e.g., combustion)

**energy resources** geologic resources, including coal, petroleum, natural gas, and nuclear fuel, used for light, heat, and power

**enforcement** EPA, state, or local legal actions to obtain compliance with environmental laws, rules, regulations, or agreements and/or obtain penalties or criminal sanctions for violations. Enforcement procedures may vary, depending upon the requirements of environmental laws and related implementing regulations. Under CERCLA, for example, the EPA will seek to require potentially responsible parties (PRPs) to clean up a Superfund site or pay for the cleanup, whereas under the Clean Air Act the agency may invoke sanctions against cities failing to meet ambient air quality standards that could prevent certain types of construction or federal funding. In other situations, if investigations by the EPA and state agencies uncover willful violations, criminal trials and penalties are sought

**Enforcement Decision Document (EDD)** a document that provides an explanation to the public of EPA's selection of the cleanup alternative at enforcement sites on the National Priorities List. Similar to a Record of Decision (ROD)

**engineered controls** method of managing environmental and health risks by placing a barrier between the contamination and the rest of the site, thus limiting exposure pathways

**enrichment** the addition of nutrients (e.g., nitrogen, phosphorus, carbon compounds) from sewage effluent or agricultural runoff to surface water. It greatly increases the growth potential for algae and other aquatic plants

**entrain** to trap bubbles in water either mechanically through turbulence or chemically through a reaction

**environmental assessment** an environmental analysis prepared following the guidelines of the National Environmental Policy Act to determine whether a federal action would significantly affect the environment and thus require a more detailed Environmental Impact Statement

**environmental audit** an independent assessment of the current status of a party's compliance with applicable environmental requirements or of a party's environmental compliance policies, practices, and controls

**environmental exposure** human exposure to pollutants originating from facility emissions. Threshold levels are not necessarily surpassed, but low-level chronic pollutant exposure is one of the most common forms of environmental exposure

**environmental fate** the destiny of a chemical or biological pollutant after release into the environment

**environmental fate data** data that characterize a pesticide's fate in the ecosystem, considering factors that foster its degradation (light, water, microbes), pathways, and resultant breakdown products

**Environmental Impact Statement (EIS)** a document required of federal agencies by the National Environmental Policy Act for major projects or legislative proposals that significantly affect the environment. A tool for decision making, it describes the positive and negative effects of the undertaking and explains alternative actions

**environmental indicator** a measurement, statistic, or value that provides a proximate gauge or evidence of the effects of environmental management programs or of the state or condition of the environment

**environmental justice (EJ, environmental equity)** equal protection from environmental hazards for individuals, groups, or communities regardless of race, ethnicity, or economic status. This applies to the development, implementation, and enforcement of environmental laws, regulations, and policies and implies that no population of people should be forced to shoulder a disproportionate share of negative environmental impacts of pollution or environmental hazard because of lack of political or economic influence. The fair treatment of people of all races, cultures, incomes, and educational levels with respect to the development and enforcement of environmental laws, regulations, and policies

**environmental lien** a charge, security, or encumbrance on a property's title to secure payment of cost or debt arising from response actions, cleanup, or other remediation of hazardous substances or petroleum products

**environmental medium** an environmental system (e.g., surface water, groundwater, soil, or air) that surrounds or contacts humans, animals, plants, and other organisms and through which chemicals or pollutants move

**environmental response team** EPA experts located in Edison, New Jersey, and Cincinnati, Ohio, who can provide around-the-clock technical assistance to EPA regional offices and states during all types of hazardous waste site emergencies and spills of hazardous substances

**environmental risk or ecological risk** the potential for adverse effects on living organisms associated with pollution of the environment by effluents, emissions, wastes, or accidental chemical releases; energy use; or the depletion of natural resources

**environmental site assessment** the process of determining whether contamination is present on a parcel of real estate as well as its condition

**environmental sustainability** long-term maintenance of ecosystem components and functions for future generations

**enzyme** a biological compound that catalyzes a specific biochemical reaction

**epicenter** the point on the Earth's surface directly above the focus of an earthquake

**epilimnion** upper waters of a thermally stratified lake affected by wind action

**episode (pollution)** an air pollution incident in a given area caused by a concentration of atmospheric pollutants under meteorological conditions that may result in a significant increase in illnesses or deaths. May also describe water pollution events or hazardous material spills

**equilibrium** in relation to radiation, the state at which the radioactivity of consecutive elements within a radioactive series is neither increasing nor decreasing. In chemistry, a state in which the tendency of reactants to form products is balanced by the tendency of products to form reactants

**equivalent method** any method of sampling and analyzing for air, water, or soil pollution that has been demonstrated to the EPA administrator's satisfaction to be, under specific conditions, an acceptable alternative to normally used reference methods

**erosion** the wearing away of land surface by wind, water, or ice, intensified by land-clearing prac-

- tices related to farming, residential or industrial development, roadbuilding, or logging
- error** the difference between the measured result and the true value
- estuary** region of interaction between rivers and near-shore ocean waters, where tidal action and river flow mix freshwater and salt water. Such areas include bays, mouths of rivers, salt marshes, and lagoons. These brackish water ecosystems shelter and feed marine life, birds, and wildlife
- ethanol** an alternative automotive fuel derived from grain and corn; usually blended with gasoline to form gasohol
- eustatic sea level change** a global change in sea level. Causes include the growth or melting of glaciers and variations in water temperature
- eutrophic lakes** shallow, murky bodies of water with concentrations of plant nutrients causing excessive production of algae
- evaporation** the change of molecules from the liquid phase into the gas phase
- evaporation ponds** areas where sewage sludge is spread out and dried
- exceedance** violation of the pollutant levels permitted by environmental protection standards
- exclusionary ordinance** zoning that excludes classes of persons or businesses from a particular neighborhood or area
- exempted aquifer** underground water-carrying bodies defined in the Underground Injection Control program as aquifers that are potential sources of drinking water though not being used as such and, thus, exempted from regulations barring underground injection activities
- exemption** a state (with primacy) may exempt a public water system from a requirement involving a maximum contaminant level (MCL), treatment technique, or both, if the system cannot comply as a result of compelling economic or other factors, or because the system was in operation before the requirement or MCL was instituted; and the exemption will not create a public health risk
- exempt solvent** specific organic compounds not subject to requirements of regulation because they are deemed by EPA to be of negligible photochemical reactivity
- exothermic reaction** a reaction that releases heat to the surroundings
- exotic species** a species that is not indigenous to a region
- experimental use permit** obtained by manufacturers for testing new pesticides or new uses for existing pesticides. Required whenever they conduct experimental field studies to support registration on 10 acres (4.05 ha) or more of land or one acre (0.4 ha) or more of water
- explosive limits** the amounts of vapor in the air that form explosive mixtures; limits are expressed as lower and upper limits and give the range of vapor concentrations in air that will explode if an ignition source is present
- exports** in solid waste programs, municipal solid waste and recyclables transported outside the state or locality where they originated
- exposure** the amount of radiation or pollutant present in a given environment that represents a potential health threat to living organisms
- exposure assessment** identifying the pathways by which toxicants may reach individuals, estimating how much of a chemical an individual is likely to be exposed to, and estimating the number of individuals likely to be exposed
- exposure concentration** the concentration of a chemical or other pollutant representing a health threat in a given environment
- exposure indicator** a characteristic of the environment measured to provide evidence of the occurrence or magnitude of a response indicator's exposure to a chemical or biological stress
- exposure level** the amount (concentration) of a chemical at the absorptive surfaces of an organism
- exposure pathway** the path from sources of pollutants via soil, water, or food to humans and other species or settings
- exposure-response relationship** the relationship between exposure level and the incidence (occurrence) of adverse effects
- exposure route** the way a chemical or pollutant enters an organism after contact (i.e., by ingestion, inhalation, or dermal absorption)
- extensive properties (of matter)** those that depend upon the specific sample that is under observation (e.g., weight, volume)
- externalities** the direct and indirect costs associated with living in a degraded environment. Includes increased medical costs, lowered land values, higher energy costs, and so on
- extraction procedure (EP Toxic)** determining toxicity by a procedure that simulates leaching; if a certain concentration of a toxic substance can be leached from a waste, that waste is considered hazardous (i.e., EP Toxic)
- extraction well** a well used to remove and discharge groundwater or air to a treatment process or the environment

**extremely hazardous substances** any of 406 chemicals identified by EPA as toxic and listed under SARA Title III. The list is subject to periodic revision

**fabric filter** a cloth device that catches dust particles from industrial emissions, usually used in a baghouse See BAGHOUSE FILTER

**facultative bacteria** bacteria that can live under aerobic or anaerobic conditions

**fault** a fracture in rock along which movement has occurred. Faults generate earthquakes

**feasibility study** analysis of the practicability of a proposal. A description and analysis of potential cleanup methods for a polluted site such as one on the National Priorities List. The feasibility study usually recommends selection of a cost-effective alternative and starts as soon as the remedial investigation (RI) is under way. Together, both processes commonly are referred to as the "RI/FS"

**fecal coliform bacteria** bacteria found in the intestinal tracts of mammals. Their presence in water or sludge is an indicator of pollution and possible contamination by pathogens

**Federal Implementation Plan** under current law, a federally implemented plan to achieve attainment of air quality standards, used when a state is unable to develop an adequate plan

**Federal Motor Vehicle Control Program** all federal actions aimed at controlling pollution from motor vehicles by such efforts as establishing and enforcing tailpipe and evaporative emission standards for new vehicles, testing methods development, and guidance to states operating inspection and maintenance programs

**feedlot** a confined area for the controlled feeding of animals. Tends to concentrate large amounts of animal waste that cannot be absorbed by the soil and, hence, may be carried to nearby streams or lakes by storm-water runoff

**fen** a type of wetland that accumulates peat deposits. Fens are less acidic than bogs, deriving most of their water from groundwater rich in calcium and magnesium

**ferrous metals** metals that include a component of iron such as steel, pig iron, and alloys that contain iron. Products made from ferrous metals include appliances, furniture, containers, and packaging such as steel drums and barrels. Recycled products include processing tin/steel cans, strapping, and metals from appliances into new products

**FIFRA pesticide ingredient** an ingredient of a pesticide that must be registered with EPA under the Federal Insecticide, Fungicide, and Rodenti-

cide Act. Products making pesticide claims must register under FIFRA and may be subject to labeling requirements and use restrictions

**fill** synthetic deposits of natural soils or a combination of natural soils, rocks, rock products, and waste materials

**filling** depositing soil, mud, or other materials into aquatic areas to create dry land, usually for agricultural or commercial development purposes. Filling often destroys the indigenous ecological resources of the area being developed

**filter strip** narrow elongated region, strip, or area of vegetation used for removing sediment, organic matter, and other pollutants from runoff and wastewater

**filtration** a treatment process, under the control of qualified operators, for removing solid (particulate) matter from water by means of porous media such as sand or a synthetic filter; often used to remove particles that contain pathogens

**Financial Assurance for Closure** documentation or proof that an owner or operator of a facility such as a landfill or other waste repository is capable of paying the projected costs associated with closing the facility and monitoring it afterward as provided in RCRA regulations

**Finding of No Significant Impact (FoNSI)** a document prepared by a federal agency showing why a proposed action would not have a significant impact on the environment and, thus, would not require preparation of an Environmental Impact Statement. A FoNSI is based on the results of an environmental assessment

**finished water** potable water that has passed through all the processes in a water treatment plant and is ready to be delivered to consumers

**first draw** potable water that flows out when a tap is first opened, likely to have the highest level of lead contamination from plumbing materials

**fission** the breakdown of an atomic nucleus of an element of relatively high atomic number into two or more nuclei of lower atomic number, with conversion of part of the mass to energy

**fix a sample** addition of chemicals to a sample that prevents water quality indicators of interest in the sample from changing before laboratory measurements are made

**fixed-location monitoring** sampling of an environmental or ambient medium (air or water) for pollutant concentration at one location continuously or repeatedly

**flammable** any material that ignites easily and burns rapidly

**flare** a control device that ignites and burns hazardous materials to prevent their release into the

environment; may operate continuously or intermittently, usually on top of a stack

**flash point** the lowest temperature at which evaporation of a substance produces sufficient vapor to form an ignitable mixture with air

**floc** a clump of solids formed in sewage by biological or chemical action

**flocculation** process by which clumps of solids in water or sewage aggregate through biological or chemical action so they can be separated from water or sewage

**floodplain** the flat or nearly flat land along a river or stream or in a tidal area that is covered by water during a flood

**floor sweep** capture of heavier-than-air gases that collect at floor level

**flowable** pesticide and other formulations in which the active ingredients are finely ground insoluble solids suspended in a liquid. They are mixed with water for application

**flowmeter** a gauge or instrument that measures the velocity of wastewater moving through a treatment plant or of any liquid moving through various industrial processes

**flow rate** the rate at which a medium flows. In environmental work, it is the rate at which a fluid escapes from a hole or fissure in a tank in gallons or liters per hour. Such measurements also are made of liquid waste, effluent, and surface water movement

**flue gas** the exhaust out of a chimney after combustion in the burner it is venting. It can include nitrogen oxides, carbon oxides, water vapor, sulfur oxides, particles, and many other chemical pollutants

**flue gas desulfurization** a technology that employs a material, usually lime or limestone, to remove sulfur dioxide chemically from the gases produced by burning fossil fuels. Flue gas desulfurization is current state-of-the-art technology for major SO<sub>2</sub> emitters, such as power plants

**fluidized** a mass of solid particles that is made to flow as a liquid by injection of water or gas. In water treatment, a bed of filter medium is fluidized by backwashing water through the filter

**fluidized bed incinerator** an incinerator that uses a bed of hot sand or other granular material to transfer heat directly to waste. Used mainly for destroying municipal sludge

**flume** a natural or synthetic channel that diverts water

**fluoridation** the addition of a chemical to increase the concentration of fluoride ions in drinking water to reduce the incidence of tooth decay

**fluorides** gaseous, solid, or dissolved compounds containing fluorine that result from industrial processes. Excessive amounts in food can lead to fluorosis

**fluorocarbons (FCs)** any of a number of organic compounds analogous to hydrocarbons in which one or more hydrogen atoms are replaced by fluorine. Once used in the United States as a propellant for domestic aerosols, they are now found mainly in coolants and some industrial processes. FCs containing chlorine are called chlorofluorocarbons (CFCs). They are believed to be modifying the ozone layer in the stratosphere, thereby allowing harmful ultraviolet radiation to reach the Earth's surface

**flush** to open a cold-water tap to clear out all the water that may have been sitting for a long time in the pipes. In new homes, to flush a system means to send large volumes of water gushing through the unused pipes to remove loose particles of solder and flux. Also, to force large amounts of water through a system to clean out piping or tubing, storage or process tanks

**fly ash** noncombustible (i.e., mineral) residual particles expelled by flue gas. Eventually fly ash settles to the ground as a gritty dust

**focus** the belowground, rupture point of a fault that produces an earthquake

**fog** a cloud that forms at or very close to ground level

**fogging** applying a pesticide by rapidly heating the liquid chemical so that it forms very fine droplets that resemble smoke or fog. Used to destroy mosquitoes, black flies, and similar pests

**food chain** a sequence of organisms, each of which uses the next, lower member of the sequence as a food source

**food processing waste** food residues produced during agricultural and industrial operations

**food waste** uneaten food and food preparation wastes from residences and commercial establishments such as grocery stores, restaurants, and produce stands; institutional cafeterias and kitchens; and industrial sources such as employee lunchrooms

**food web** the feeding relationships by which energy and nutrients are transferred from one species to another

**formulation** the substances composing all active and inert ingredients in a pesticide

**fossil fuel** fuel derived from the remains of ancient organisms (e.g., peat, coal, crude oil, and natural gas)

**fracture** a break in a rock caused by structural stresses (e.g., faults, joints, and planes of fracture cleavage)

- freeboard** vertical distance from the usual water surface to the top of a confining wall. Also, the vertical distance from the sand surface to the underside of a trough in a sand filter
- free product** a petroleum hydrocarbon in the liquid-free or nonaqueous phase
- frequency** the number of complete wave cycles, from crest to crest, that pass by any given point in a second
- freshwater** water that generally contains less than 1,000 milligrams per liter of dissolved solids
- friable** capable of being crumbled, pulverized, or reduced to powder by hand pressure
- friable asbestos** any material containing more than 1 percent asbestos that can be crumbled or reduced to powder by hand pressure. May include previously nonfriable material that is broken or damaged by mechanical force
- fuel efficiency** the proportion of energy released by fuel combustion that is converted into useful energy
- fuel rod** a 6.56-foot (2-m) column of uranium pellets used as the fission source in a nuclear reactor
- fuel switching** a precombustion process whereby a low-sulfur coal is used in place of a higher-sulfur coal in a power plant to reduce sulfur dioxide emissions. Also, illegally using leaded gasoline in a motor vehicle designed to use only unleaded
- fugitive emissions** emissions not caught by a capture system
- fume** tiny particles trapped in vapor in a gas stream
- fumigant** a pesticide vaporized to kill pests. Used in buildings and greenhouses
- functional equivalent** term used to describe EPA's decision-making process and its relationship to the environmental review conducted under the National Environmental Policy Act (NEPA). A review is considered functionally equivalent when it addresses the substantive components of NEPA
- functional group** an atom or small group of atoms in a molecule that undergo characteristic reactions
- fungicide** pesticide that is used to control, deter, or destroy fungi
- fungistat** a chemical that prevents fungi from growing
- fungus (fungi)** molds, mildews, yeasts, mushrooms, and puffballs, a group of organisms lacking chlorophyll (i.e., not photosynthetic), which usually are nonmobile, filamentous, and multicellular. Some grow in soil; others attach themselves to decaying trees and plants, whence they obtain nutrients. Some are pathogens; others stabilize sewage and digest composted waste
- furrow irrigation** irrigation method in which water travels through the field by means of small channels between groups of rows
- fusion** the combination of nuclei of light elements (particularly hydrogen) to form heavier nuclei. This process results in the release of energy (i.e., heat)
- future liability** refers to potentially responsible parties' obligations to pay for additional response activities beyond those specified in the Record of Decision or Consent Decree
- Gaia hypothesis** concept that Earth behaves as a single self-sustaining and self-regulating system or super-organism and that living things interact in a way that stabilizes the climate and allows life to flourish
- garbage** animal and vegetable waste resulting from the handling, storage, sale, preparation, cooking, and serving of foods
- gasahol** mixture of gasoline and ethanol derived from fermented agricultural products containing at least 9 percent ethanol. Gasahol emissions contain less carbon monoxide than those from gasoline
- gas chromatograph/mass spectrometer (GC/MS)** instrument that identifies the molecular composition and concentrations of trace amounts of elements in organic chemicals in water and soil samples
- gasification** conversion of solid material such as coal into a gas for use as a fuel
- gasoline volatility** the property of gasoline whereby it evaporates into a vapor. Gasoline vapor is a mixture of volatile organic compounds (VOCs)
- generally recognized as safe (GRAS)** designation by the Food and Drug Administration that a chemical or substance (including certain pesticides) added to food is considered safe by experts and so is exempted from food additive limits
- generator** a facility or mobile source that emits pollutants into the air or releases hazardous waste into water or soil. Also, any person (by site) whose act or process produces regulated medical waste or whose act first causes such waste to become subject to regulation
- genetic engineering** a process of inserting new genetic information into existing cells in order to modify a specific organism for the purpose of changing one of its characteristics
- genotoxic** damaging to deoxyribonucleic acid (DNA) or pertaining to agents known to damage DNA
- Geographic Information System (GIS)** a computer system designed for storing, manipulating,

- analyzing, and displaying data in a geographic context. A spatial database management system
- geologic column** a composite diagram that shows the sequence of rocks at a given place or region arranged to show their position and ages. A stratigraphic column
- geologic log** a detailed description of all underground soil and rock features (depth, thickness, type of formation) encountered during the drilling of a well
- geosphere** the Earth from its center (core) to outer crust
- geothermal energy** energy derived from the heat of the Earth
- geothermal gradient** the rate at which temperature increases with depth below ground surface
- geothermal/ground source heat pump** underground coils used to transfer heat from the ground to the inside of a building
- germicide** any compound that kills disease-causing microorganisms
- glass containers** for recycling purposes, containers such as bottles and jars for drinks, food, cosmetics, and other products. When being recycled, container glass is generally separated into color categories for conversion into new containers, construction materials, or fiberglass insulation
- Global Positioning System (GPS)** a system using satellite telemetry to determine the exact location of a receiver or GPS unit on the ground. The system determines latitude, longitude, and altitude by triangulation from multiple satellites
- global warming potential (GWP)** the ratio of the warming caused by a substance to the warming caused by a similar mass of carbon dioxide. CFC-12, for example, has a GWP of 8,500, whereas water has a GWP of 0
- glovebag** a polyethylene or polyvinyl chloride bag-like enclosure affixed around an asbestos-containing source (most often thermal system insulation) permitting the material to be removed while minimizing release of airborne fibers to the surrounding atmosphere
- gooseneck** a portion of a water service connection between the distribution system water main and a meter. Sometimes called a pigtail
- grab sample** a single sample collected at a particular time and place that represents the composition of the water, air, or soil only at that time and place
- graded stream** a stream with a concave profile that is in equilibrium with its sediment supply; it transports all the sediment supplied to it with neither erosion of nor deposition within the stream bed
- gradient** the vertical drop of water level over a given distance within a stream bed or aquifer
- granular activated carbon treatment (GAC)** a filtering system often used in low-flow water systems and individual homes to remove organics. Although expensive to use on a large scale, GAC can be highly effective in lowering elevated levels of organic chemicals and radon in water
- grassed waterway** natural or constructed watercourse or outlet that is shaped or graded and established in suitable vegetation for the disposal of runoff water without erosion
- gray water** domestic wastewater composed of wash water from kitchen, bathroom, and laundry sinks, tubs, and washers
- greenhouse effect** the warming of the Earth's atmosphere attributed to a buildup of carbon dioxide or other gases. This buildup allows the Sun's rays to heat the Earth, while reducing the ability of the atmosphere to dissipate reradiated energy associated with surface heating. Also, the effect of a blanket of gases that insulate the Earth and prevent it from radiating heat
- gross alpha or beta particle activity** the total radioactivity due to alpha or beta particle emissions as inferred from measurements on a dry sample
- ground cover** plants grown to prevent soil from eroding
- ground-penetrating radar (GPR)** a geophysical method that uses high-frequency electromagnetic waves to obtain subsurface information
- Ground-Water Disinfection Rule** a 1996 amendment of the Safe Drinking Water Act requiring EPA to promulgate national primary drinking water regulations requiring disinfection for all public water systems, including surface waters and groundwater systems
- gully erosion** severe erosion in which trenches are cut to a depth greater than one foot (30 cm). Generally, ditches deep enough to cross with farm equipment are considered gullies
- habitat** the place where a population (e.g., human, animal, plant, microorganism) lives and its surroundings, both living and nonliving
- habitat indicator** a physical attribute of the environment measured to characterize conditions necessary to support an organism, population, or community in the absence of pollutants
- half-life** the time required for a pollutant to lose one-half of its original concentration. For radioactive compounds, the time required for half of the atoms of a radioactive element to undergo decay
- halon** bromine-containing compounds with long atmospheric lifetimes whose breakdown in the

stratosphere causes depletion of ozone. Halons are used in firefighting

**hammer mill** a high-speed machine that uses hammers and cutters to crush, grind, chip, or shred solid waste

**hard water** alkaline water containing dissolved salts that interfere with some industrial processes and prevent soap from forming suds

**hazard** potential for radiation, chemical, or other pollutant to cause human illness or injury. Hazard identification of a given substance is based on verifiable toxicity data from animal models or human studies

**hazard assessment** evaluating the effects of a stressor or determining a margin of safety for an organism by comparing the concentration that causes toxic effects with an estimate of exposure to the organism

**Hazard Communication Standard** an OSHA regulation that requires chemical manufacturers, suppliers, and importers to assess the hazards of the chemicals they make, supply, or import and to inform employers, customers, and workers of these hazards through Material Safety Data Sheet information

**hazard evaluation** a component of risk evaluation that involves gathering and evaluating data on the types of health injuries or diseases that may be produced by a chemical and on the conditions of exposure under which such health effects are produced

**hazard identification** determining whether a chemical or a microbe can cause adverse health effects in humans and what those effects might be

**hazardous air pollutants** air pollutants that are not covered by ambient air quality standards but that, as defined in the Clean Air Act, may present a threat of adverse human health effects or adverse environmental effects. Such pollutants include asbestos, beryllium, mercury, benzene, coke oven emissions, radionuclides, and vinyl chloride

**Hazardous Chemical** an EPA designation for any hazardous material requiring an MSDS under OSHA's Hazard Communication Standard. Such substances are capable of producing fires and explosions or adverse health effects including cancer and dermatitis. Hazardous chemicals are distinct from HAZARDOUS WASTE.

**Hazardous Ranking System (HRS)** the principal screening tool used by EPA to evaluate risks to public health and the environment associated with abandoned or uncontrolled hazardous waste sites. The HRS calculates a score based on

the potential of hazardous substances to spread from the site through the air, surface water, or groundwater and on other factors such as density and proximity of human population. This score is the primary factor in deciding whether the site should be on the National Priorities List and, if so, what ranking it should have compared to other sites on the list

**hazardous substance** any material that poses a threat to human health and/or the environment. Typical hazardous substances are toxic, corrosive, ignitable, explosive, or chemically reactive. Also, any substance designated by EPA to be reported if a designated quantity of the substance is spilled into the waters of the United States or is otherwise released into the environment

**hazardous waste** by-products of society that can pose a substantial or potential hazard to human health or the environment when improperly managed. Possesses at least one of four characteristics (ignitability, corrosivity, reactivity, or toxicity) or appears on special EPA lists

**hazardous waste landfill** an excavated or engineered site where hazardous waste is disposed

**hazardous waste minimization** reducing the amount of toxicity or waste produced by a facility via source reduction or environmentally sound recycling

**hazard quotient** the ratio of estimated site-specific exposure to a single chemical from a site over a specified period to the estimated daily exposure level at which no adverse health effects are likely to occur

**hazard ratio** a term used to compare an animal's daily dietary intake of a pesticide to its LD50 value. A ratio greater than 1.0 indicates that the animal is likely to consume a dose that would kill 50 percent of animals of the same species

**hazards analysis** procedures used to identify potential sources of release of hazardous materials from fixed facilities or transportation accidents, to determine the vulnerability of a geographical area to a release of hazardous materials, and to compare hazards to determine which present greater or lesser risks to a community

**hazards identification** a process to provide information on the facilities that have extremely hazardous substances, what those substances are, how much there is at each facility, how the substances are stored, and whether they are used at high temperatures

**headspace** the vapor mixture trapped above a solid or liquid in a sealed vessel

**Health Advisory Level** a nonregulatory health-based reference level of chemical traces (usually in parts per million) in drinking water at which there are no adverse health risks when ingested over various periods. Such levels are established for one day, 10 days, long-term, and lifetime exposure periods. They contain a wide margin of safety

**Health Assessment** an evaluation of available data on existing or potential risks to human health posed by a Superfund site. The Agency for Toxic Substances and Disease Registry (ATSDR) of the Department of Health and Human Services (DHHS) is required to perform such an assessment at every site on the National Priorities List

**heat island effect** a “dome” of elevated temperatures over an urban area caused by structural and pavement heat fluxes and pollutant emissions

**heat pump** an electric device with both heating and cooling capabilities. It extracts heat from one medium at a lower temperature (the heat source) and transfers it to another at a higher temperature (the heat sink), thereby cooling the first and warming the second

**heavy metals** metallic elements with high atomic weights and inorganic pollutants (e.g. arsenic, cadmium, chromium, lead, mercury, and nickel) that can damage living organisms at low concentrations and tend to accumulate in the food chain

**herbicide** a chemical pesticide designed to control or destroy plants, weeds, or grasses

**herbivore** an animal that feeds on plants

**heterotrophic organisms** species dependent on organic matter for food

**high-density polyethylene (HDPE)** a material used to make plastic bottles and other products that produces toxic fumes when burned

**highest dose tested** the highest dose of a chemical or substance tested in a study

**high-level nuclear waste facility** plant designed to handle disposal of used nuclear fuel, high-level radioactive waste, and plutonium waste

**high-line jumpers** pipes or hoses connected to fire hydrants and placed on top of the ground to provide emergency water service for an isolated portion of a distribution system

**high-risk community** a community in the vicinity of numerous sites, facilities, or other potential sources of environmental pollution that may result in high levels of exposure

**high-to-low-dose extrapolation** the process of prediction of low exposure risk to humans and animals from the measured high-exposure-high-risk data involving laboratory animals

**holding pond** a pond or reservoir, usually made of earth, built to store polluted water

**holding time** the maximum amount of time a sample may be stored before analysis

**hollow stem auger drilling** conventional drilling method that uses augers to penetrate the soil. As the augers are rotated, soil cuttings are conveyed to the ground surface via spirals or flutes. Direct push (DP) tools can be used inside the hollow augers

**homeowner water system** any water system that supplies piped water to a single residence

**host** in genetics, the organism, typically a bacterium, into which a gene from another organism is transplanted. In medicine, an animal infected or parasitized by another organism

**household hazardous waste** hazardous products used and disposed of by residential as opposed to industrial consumers. Includes paints, stains, varnishes, solvents, pesticides, and other materials or products containing volatile chemicals that can catch fire, react, or explode or that are corrosive or toxic

**household waste (domestic waste)** solid waste composed of garbage and rubbish that normally originates in a private home or apartment house. Domestic waste may contain a significant amount of toxic or hazardous waste

**human equivalent dose** a dose that, when administered to humans, produces an effect equal to that produced by a dose in animals

**human exposure evaluation** describing the nature and size of the population exposed to a substance and the magnitude and duration of their exposure

**human health risk** the likelihood that a given exposure or series of exposures may have damaged or will damage the health of individuals

**humus** the dark organic component of soil composed of leaves, roots, and other debris that have sufficiently decomposed so that the origin of the individual pieces cannot be identified

**hydration** the chemical combination of water with another substance

**hydraulic action** the mechanical loosening and removal of material by flowing water

**hydraulic conductivity** the rate at which water can move through a permeable medium

**hydraulic gradient** in general, the direction of groundwater flow due to changes in the height of the water table

**hydride** a compound of hydrogen and one or more metals that can be heated to release hydrogen gas for use as a fuel

**hydrocarbon (HC)** chemical compound that consists entirely of carbon and hydrogen

**hydrogen economy** an economic system based on the use of hydrogen as the primary source of energy, rather than petroleum

**hydrogen sulfide (H<sub>2</sub>S)** gas emitted during organic decomposition. Also, a by-product of oil refining and burning. Has an odor similar to that of rotten eggs and, in heavy concentration, can kill or cause illness

**hydrogeology** the geology of groundwater, with particular emphasis on the chemistry and movement of water and the media that contain it

**hydrologic cycle (water cycle)** the natural process recycling water from the atmosphere to and through the surface of the Earth and back to the atmosphere again. Movement or exchange of water between the atmosphere and Earth

**hydrology** the science dealing with the properties, distribution, and circulation of water

**hydrolysis** the decomposition of organic compounds by interaction with water

**hydronic** a ventilation system using heated or cooled water pumped through a building

**hydrophilic** having a strong affinity (attraction) for water

**hydrophobic** having a strong aversion to (repulsion for) water

**hydropneumatic** a water system, usually small, in which a water pump is automatically controlled by the pressure in a compressed air tank

**hydrosphere** all of the Earth's water, including the atmosphere, oceans, and within the continents

**hygroscopic** a substance with the ability to absorb water vapor directly from the air

**hypersensitivity diseases** diseases characterized by allergic responses to pollutants; diseases most clearly associated with indoor air quality are asthma, rhinitis, and pneumonic hypersensitivity

**hypolimnion** bottom waters of a thermally stratified lake. The hypolimnion of a eutrophic lake is usually low or lacking in oxygen

**hypoxia/hypoxic waters** waters with dissolved oxygen concentrations of less than two parts per million, the level generally accepted as the minimum required for most marine life to survive and reproduce

**Identification Code or EPA I.D. number** the code assigned to each generator, transporter, and treatment, storage, or disposal facility by regulating agencies to identify and track chemicals and hazardous waste

**Imhoff cone** a clear, cone-shaped container used to measure the volume of settleable solids in a specific volume of water

**Immediately Dangerous to Life and Health (IDLH)** the maximal level to which a healthy individual can be exposed to a chemical for 30 minutes without irreversible health effects or impairing symptoms

**imminent hazard** one that would be likely to result in unreasonable adverse effects on humans or the environment or risk unreasonable hazard to an endangered species during the time required for a pesticide registration cancellation proceeding

**imminent threat** a high probability that exposure to a dangerous substance is occurring

**immiscibility** the inability of two or more substances or liquids, such as oil and water, to mix readily

**impermeable** the property of a material that does not allow, or allows only with great difficulty, the movement or passage of water or gas

**impoundment** a body of water or sludge confined by a dam, dike, floodgate, or other barrier

**incident command post** a facility located at a safe distance from an emergency site, where the incident commander, key staff, and technical representatives can make decisions and deploy emergency personnel and equipment

**incineration** destruction of waste by controlled burning at high temperatures. For example, burning sludge to evaporate the water and reduce the remaining residues to a nonburnable ash that can be disposed of safely on land, in some waters, or in underground locations

**incineration at sea** disposal of waste by burning at sea on specially designed incinerator ships

**incinerator** a furnace for burning waste under controlled conditions

**incompatible waste** a waste unsuitable for mixing with another waste or material because it may react to form a hazard

**indicator** in biology, any biological entity, processes, or community whose characteristics show the presence of specific environmental conditions. In chemistry, a substance that shows a visible change, usually of color, at a desired point in a chemical reaction. Also, a device that indicates the result of a measurement (e.g., a pressure gauge or a movable scale)

**indirect discharge** introduction of pollutants from a nondomestic source into a publicly owned waste-treatment system. Indirect dischargers can be commercial or industrial facilities whose wastes enter local sewers

**indirect source** any facility or building, property, road, or parking area that attracts motor vehicle traffic and, indirectly, causes pollution

- indoor air** the breathable air inside a habitable structure
- indoor climate** temperature, humidity, lighting, airflow, and noise levels in a habitable structure. Indoor climate can affect indoor air pollution
- industrial mineral** any rock or mineral of economic importance, exclusive of metal ores, fuels, and gems. Industrial minerals include abrasives, cement, clays, sand, gravel, asbestos, vermiculite, and many others
- industrial pollution prevention** combination of industrial source reduction and toxic chemical use substitution to reduce overall emissions
- industrial process waste** waste residues produced during manufacturing operations
- industrial sludge** semiliquid residue or slurry remaining after the treatment of industrial water and wastewater
- industrial source reduction** practices that reduce the amount of any hazardous substance, pollutant, or contaminant entering a waste stream or otherwise released into the environment. Also reduces the threat to public health and the environment associated with such releases. Term includes equipment or technology modifications, substitution of raw materials, and improvements in housekeeping, maintenance, training, or inventory control
- industrial waste** unwanted materials from an industrial operation; may be liquid, sludge, solid, or hazardous waste
- inertial separator** a device that uses centrifugal force to separate waste particles
- inert ingredient** pesticide components such as solvents, carriers, dispersants, and surfactants that are not active against target pests. Not all inert ingredients are innocuous
- infectious agent** any organism, such as a pathogenic virus, parasite, or bacterium, that is capable of invading body tissues, multiplying, and causing disease
- infectious waste** hazardous waste capable of causing infections in humans, including contaminated animal waste, human blood and blood products, isolation waste, pathological waste, and discarded sharp objects (needles, scalpels, or broken medical instruments)
- infiltration** the percolation of water through the ground surface into subsurface soil or the penetration of water from the soil into sewer or other pipes through defective joints, connections, or manhole walls. Also the treatment technique of applying large volumes of wastewater to land to penetrate the surface and percolate through the underlying soil
- infiltration gallery** a subsurface groundwater collection system, typically shallow in depth, with open-jointed or perforated pipes that discharge water into a watertight chamber from which it is pumped to treatment facilities and into the distribution system. Usually located close to streams or ponds
- infiltration rate** the quantity of water that can enter the soil in a specified time interval without ponding on the surface
- inflow** entry of extraneous rainwater into a sewer system from sources other than infiltration, such as basement drains, manholes, storm drains, and street washing
- influent** water, wastewater, or other liquid flowing into a reservoir, basin, or treatment plant
- information file** in the Superfund program, a file that contains accurate, up-to-date documents on a Superfund site. The file is usually located in a public building (school, library, or city hall) convenient for local residents
- injection well** a well into which fluids are injected for purposes such as waste disposal, improving the recovery of crude oil, or solution mining
- injection zone** a geological formation receiving fluids through a well
- in-line filtration** pretreatment method in which chemicals are mixed by flowing water. Most often used in pressure filtration installations. Eliminates need for flocculation and sedimentation
- inoculum** bacteria or fungi injected into compost to start biological action. Also, a medium containing organisms, usually bacteria or virus, that are introduced into cultures or living organisms
- insecticide** a pesticide compound specifically used to kill or prevent the growth of insects.
- in situ** in its original place; unmoved; unexcavated; remaining at the site or in the subsurface
- in situ flushing** introduction of large volumes of water, at times supplemented with detergents or other cleaning compounds, into soil, waste, or groundwater to flush hazardous contaminants
- in situ (chemical) oxidation (ISCO)** technology that oxidizes contaminants dissolved in groundwater, converting them into insoluble compounds
- in situ stripping** treatment system that removes, or strips, volatile organic compounds from contaminated ground or surface water by forcing an airstream through the water and causing the compounds to evaporate

**in situ vitrification** technology that treats contaminated soil in place at extremely high temperatures, greater than 3,000°F (1,650°C)

**institutional waste** waste generated at institutions such as schools, libraries, hospitals, and prisons

**instream use** water use within a stream channel (e.g., hydroelectric power generation, navigation, water quality improvement, fish propagation, recreation)

**integrated exposure assessment** cumulative summation (over time) of the magnitude of exposure to a toxic chemical in all media

**Integrated Pest Management (IPM)** a mixture of chemical- and non-chemical-based methods to control pests

**integrated waste management** using a variety of practices to handle municipal solid waste; can include source reduction, recycling, incineration, and landfilling.

**intensity** a measure of the effects of an earthquake on buildings and other structures at a specified location

**interceptor sewers** large sewer lines that, in a combined system, control the flow of sewage to the treatment plant. In a storm, they allow some of the sewage to flow directly into a receiving stream, thus preventing it from overflowing onto the streets. Also used in separate systems to collect the flows from main and trunk sewers and carry them to treatment points

**Interim (Permit) Status** period during which treatment, storage, and disposal facilities under RCRA jurisdiction since 1980 are temporarily permitted to operate while awaiting a permanent permit. Permits issued under these circumstances are usually called Part A or Part B permits

**intermediates** a compound that is produced in one step of the reaction and then consumed in a subsequent step. Intermediates are not present in either reactants or products

**internal dose** in exposure assessment, the amount of a substance penetrating the absorption barriers (e.g., skin, lung tissue, gastrointestinal tract) of an organism through either physical or biological processes

**interstate carrier water supply** a source of water for drinking and sanitary use on planes, buses, trains, and ships operating in more than one state. These sources are federally regulated

**Interstate Commerce clause** a clause of the U.S. Constitution that reserves to the federal government the right to regulate the conduct of

business across state lines. Under this clause, for example, the U.S. Supreme Court has ruled that states may not inequitably restrict the disposal of out-of-state wastes in their jurisdictions

**interstate waters** waters that flow across or form part of state or international boundaries (e.g., the Great Lakes, the Mississippi River, or coastal waters)

**interstitial monitoring** the continuous surveillance of the space between the walls of a double-walled underground storage tank

**in vitro** testing or action outside an organism (e.g., inside a test tube or culture dish)

**in vivo** testing or action inside an organism

**ion** an electrically charged atom or group of atoms

**ion exchange treatment** a common water-softening method often on a large scale at water purification plants to remove some organics and radium by adding calcium oxide or calcium hydroxide to increase the pH to a level where the metals precipitate

**ionization** the separation of a molecular compound into individual cations and anions that are dissolved in water

**ionization chamber** a device that measures the intensity of ionizing radiation

**ionizing radiation** radiation that can strip electrons from atoms (e.g. alpha, beta, and gamma radiation). Causes cellular damage

**IRIS** EPA's Integrated Risk Information System, an electronic database containing the agency's latest descriptive and quantitative regulatory information on chemical constituents

**irradiated food** food subject to brief radioactivity, usually gamma rays, to kill insects, bacteria, and mold and to permit storage without refrigeration

**irradiation** exposure to radiation of wavelengths shorter than those of visible light (gamma, X-ray, or ultraviolet), to perform medical procedures, to sterilize milk or other foodstuffs, or to induce polymerization of monomers or vulcanization of rubber

**irreversible effect** effect characterized by the inability of the body to repair injury caused by a toxic agent partially or fully

**irrigation** applying water or wastewater to land areas to supply the moisture and nutrient needs of plants

**irrigation efficiency** the amount of water stored in the crop root zone compared to the amount of irrigation water applied

**irrigation return flow** surface and subsurface water that leaves the field after application of irrigation water

- irritant** a substance that can cause irritation of the skin, eyes, or respiratory system. Effects may be acute from a single high-level exposure or chronic from repeated low-level exposures to such compounds as chlorine, nitrogen dioxide, and nitric acid
- isoconcentration** more than one sample point exhibiting the same concentration
- isomers** different compounds with the same molecular formula but with different structural formulas
- isopleth** the line made by connecting isoconcentration points
- isotope** a variation of an element that has the same atomic number of protons but a different atomic weight because of the number of neutrons. Various isotopes of the same element may have different radioactive behaviors; some are highly unstable
- isotropy** the condition in which the hydraulic or other properties of an aquifer are the same in all directions
- jar test** a laboratory procedure that simulates a water treatment plant's coagulation/flocculation units with differing chemical doses, mix speeds, and settling times to estimate the minimal or ideal coagulant dose required to achieve certain water quality goals
- joint and several liability** under CERCLA, this legal concept relates to the liability for Superfund site cleanup and other costs of more than one potentially responsible party (PRP) if there were several owners or users of a site that became contaminated over the years. They could all be considered potentially liable for site remediation
- kerogen** the material that yields oil when an oil shale is heated and distilled. It is a precursor of liquid petroleum
- kinetic rate coefficient** a number that describes the rate at which a water constituent such as a biochemical oxygen demand or dissolved oxygen rises or falls, or at which an air pollutant reacts
- Koeppen Climate System** a widely used climate classification system
- Kyoto Protocol** an 1997 international agreement drafted in Kyoto, Japan, whose goal was to reduce emission of six greenhouse gases to 1990 levels by the year 2012. The United States did not ratify this treaty
- lagoon** a shallow pond where sunlight, bacterial action, and oxygen work to purify wastewater; also used for storage of wastewater or spent nuclear fuel rods. In oceanography, a shallow body of water, often separated from the sea by coral reefs or sandbars
- land application** discharge of wastewater onto the ground for treatment or reuse
- Land Ban** phasing out of land disposal (burial) of most untreated hazardous wastes, as mandated by the 1984 RCRA amendments
- land disposal restrictions** rules that require hazardous wastes to be treated before disposal (burial) on land to destroy or immobilize hazardous constituents that might migrate into soil and groundwater
- land farming (of waste)** a disposal process in which hazardous waste deposited on or in the soil is degraded naturally by microbes
- landscape** the traits, patterns, and structure of a specific geographic area, including its biological composition, its physical environment, and its anthropogenic or social patterns
- landscape ecology** the study of the distribution patterns of communities and ecosystems, the ecological processes that affect those patterns, and changes in pattern and process over time
- landscape indicator** a measurement of the landscape, calculated from mapped or remotely sensed data, used to describe spatial patterns of land use and land cover across a geographic area. Landscape indicators may be useful as measures of certain kinds of environmental degradation such as forest fragmentation
- Langelier Index (LI)** an index reflecting the equilibrium pH of water with respect to calcium and alkalinity; used in stabilizing water to control both corrosion and scale deposition
- large quantity generator** person or facility generating more than 2,200 pounds (1,000 kg) of hazardous waste per month. Such generators produce about 90 percent of the nation's hazardous waste and are subject to all RCRA requirements
- large water system** a water system that serves more than 50,000 customers
- laser induced fluorescence** a method for measuring the relative amount of soil and/or groundwater with an in situ sensor
- latency** time from the first exposure of a chemical until the appearance of a toxic effect
- lateral sewers** pipes that lie under city streets and receive the sewage from homes and businesses, as opposed to domestic feeders and main trunk lines
- laundering weir** sedimentation basin or overflow weir
- LC50/lethal concentration** median level concentration, a standard measure of toxicity. It indicates how much of a substance is needed to kill

half of a group of experimental organisms in a given time

**LD50/lethal dose** the dose of a toxicant or microbe that will kill 50 percent of the test organisms within a designated period. The lower the LD50, the more toxic the compound

**ldlo** lethal dose low; the lowest dose in an animal study at which lethality occurs

**leachate collection system** a system that gathers leachate and pumps it to the surface for treatment

**leaching** the process by which soluble constituents are dissolved and filtered through the soil by a percolating fluid

**Legionella** a genus of bacteria, some species of which have caused a type of pneumonia called Legionnaires' disease

**level of concern (LOC)** the concentration in air of an extremely hazardous substance above which there may be serious immediate health effects to anyone exposed to it for short periods

**life cycle of a product** all stages of a product's development, from extraction of fuel for power to production, marketing, use, and disposal

**lifetime average daily dose** value that estimates excess lifetime cancer risk

**lifetime exposure** total amount of exposure to a substance that a human would receive in a lifetime (usually assumed to be 70 years)

**lift** in a sanitary landfill, a compacted layer of solid waste and the top layer of cover material

**light nonaqueous phase liquid (LNAPL)** a nonaqueous phase liquid with a specific gravity less than 1.0. The specific gravity of water is 1.0 so LNAPL floats on top of the water table. Most common petroleum hydrocarbon fuels and lubricating oils are LNAPLs

**limestone scrubbing** use of a limestone and water solution to remove gaseous stack-pipe sulfur before it reaches the atmosphere

**limited degradation** an environmental policy permitting some degradation of natural systems but terminating at a level well below an established health standard

**limiting factor** a condition whose absence or excessive concentration is incompatible with the needs or tolerance of a species or population, and that may have a negative influence on their ability to thrive

**limiting reactant** a reactant that is completely consumed in a chemical reaction

**limit of detection (LOD)** the minimal concentration of a substance being analyzed that has a 99 percent probability of being identified

**liner** a relatively impermeable barrier designed to keep leachate inside a landfill. Liner materials

include plastic and dense clay. Also, an insert or sleeve for sewer pipes to prevent leakage or infiltration

**lipid solubility** the maximal concentration of a chemical that will dissolve in fatty substances. Lipid-soluble substances are insoluble in water. They selectively disperse through the environment via uptake in living tissue

**liquid injection incinerator** commonly used system that relies on high pressure to prepare liquid wastes for incineration by breaking them up into tiny droplets to allow easier combustion

**listed waste** wastes listed as hazardous under RCRA but not subjected to the Toxic Characteristics Listing Process because the dangers they present are considered self-evident

**lithification** the process of converting loose sediment to solid rock

**litter** the highly visible portion of solid waste carelessly discarded outside the regular garbage and trash collection and disposal system. Also, leaves and twigs fallen from forest trees

**littoral zone** that portion of a body of freshwater extending from the shoreline lakeward to the limit of occupancy of rooted plants. Also, a strip of land along the shoreline between the high and low water levels

**Local Emergency Planning Committee (LEPC)** a committee appointed by the state emergency response commission, as required by SARA Title III, to formulate a comprehensive emergency plan for its jurisdiction

**low-density polyethylene (LDPE)** plastic material used for both rigid containers and plastic film

**lower detection limit** the smallest presence of a contaminant that an analytical instrument can reliably detect

**lower explosive limit (LEL)** the concentration of a compound in air below which the mixture will not catch on fire

**lowest acceptable daily dose** the largest quantity of a chemical that will not cause a toxic effect, as determined by animal studies

**lowest achievable emission rate** under the Clean Air Act, the most stringent limits on rate of emissions in a state implementation plan for any source unless the owner demonstrates such limitations are not achievable, or the most stringent emissions limitation achieved in practice, whichever is more stringent

**lowest observed adverse effect level (LOAEL)** the lowest level of a stressor that causes significant differences in test samples

**low-input agriculture** farming that uses lower amounts of pesticides, fertilizers, growth hormones, water, and fossil fuel than are used in current practices

**low-level radioactive waste (LLRW)** wastes less hazardous than most of those associated with a nuclear reactor; generated by hospitals, research laboratories, and certain industries. The Department of Energy, Nuclear Regulatory Commission, and EPA share responsibilities for managing them

**low NOx burners** one of several combustion technologies used to reduce emissions of nitrogen oxides (NOx)

**macropores** secondary soil features such as root holes or desiccation cracks that can create significant conduits for movement of NAPL and dissolved or vapor-phase contaminants. See NONAQUEOUS PHASE LIQUID

**magnetic separation** use of magnets to separate ferrous materials from mixed municipal waste

**magnitude** a measure of the energy released by an earthquake

**major modification** changes to major stationary sources of emissions with respect to Prevention of Significant Deterioration and New Source Review under the Clean Air Act

**majors** larger publicly owned treatment works (POTWs) with flows equal to at least 1 million gallons (3.8 million L) per day (md) or serving a population equivalent to 10,000 persons; certain other POTWs having significant water quality impacts

**major stationary sources** under the Clean Air Act, term used to determine the applicability of Prevention of Significant Deterioration (PSD) and new source regulations. In a nonattainment area, any stationary pollutant source with potential to emit more than 100 tons (91 metric tons) per year is considered a major stationary source. In PSD areas, the cutoff level may be either 100 or 250 tons (91 or 227 metric tons), depending upon the source

**management plan** under the Asbestos Hazard Emergency Response Act (AHERA), a document that each local education agency is required to prepare, describing all activities planned and undertaken by a school to comply with AHERA regulations, including building inspections to identify asbestos-containing materials, response actions, and operations and maintenance programs to minimize the risk of exposure

**manifest** a one-page form used by haulers transporting waste that lists the EPA identification numbers, the type and quantity of waste, the generator when it originated, the transporter

that shipped it, and the storage or disposal facility to which it is being shipped. It includes copies for all participants in the shipping process

**manifest system** tracking of hazardous waste from generation through disposal ("cradle-to-grave") with accompanying manifest documents

**margin of exposure (MOE)** the ratio of the no-observed-adverse-effect-level to the estimated exposure dose

**margin of safety** maximum amount of exposure producing no measurable effect in animals (or studied humans) divided by the actual amount of human exposure in a population

**marine protected area** a region of the ocean set aside to protect marine life from fishing pressure

**marine reserve** an area of the ocean where no fishing is allowed

**marine sanitation device** any equipment or process installed on a vessel to receive, retain, treat, or discharge sewage

**marsh** a type of wetland that does not accumulate appreciable peat deposits and is dominated by vegetation. Marshes may be freshwater or salt water, tidal or nontidal

**material safety data sheet (MSDS)** a compilation of information required under the OSHA Communication Standard on the identity of hazardous chemicals, health and physical hazards, exposure limits, and precautions. Section 311 of SARA requires facilities to submit MSDSs under certain circumstances

**materials recovery facility (MRF)** a facility that processes residually collected mixed recyclables into new products available for market

**maximally (or most) exposed individual** the person with the highest exposure in a given population

**Maximum Acceptable Toxic Concentration** for a given ecological effects test, the range (or geometric mean) between the No Observable Adverse Effect Level and the Lowest Observable Adverse Effects Level

**Maximum Available Control Technology (MACT)** the emission standard for sources of air pollution requiring the maximal reduction of hazardous emissions, taking cost and feasibility into account. Under the Clean Air Act Amendments of 1990, the MACT must not be less than the average emission level achieved by controls on the best performing 12 percent of existing sources, by category of industrial and utility sources

**maximum contaminant level (MCL)** the maximal permissible level of a contaminant in water delivered to any user of a public system. MCLs are enforceable standards

**maximum contaminant level goal (MCLG)** under the Safe Drinking Water Act, a nonenforceable concentration of a drinking water contaminant, set at the level at which no known or anticipated adverse effects on human health occur and that allows an adequate safety margin. The MCLG is usually the starting point for determining the regulated Maximum Contaminant Level (MCL)

**maximum exposure range** estimate of exposure or dose level received by an individual in a defined population that is greater than the 98th percentile dose for all individuals in that population, but less than the exposure level received by the person receiving the highest exposure level

**maximum residue level** the enforceable limit on food pesticide levels in some countries. Levels are set by the Codex Alimentarius Commission, a United Nations agency managed and funded jointly by the World Health Organization and the Food and Agriculture Organization

**maximum sustainable yield** the most a renewal resource can be exploited while still leaving it available for future generations

**maximum tolerated dose** the maximum dose that an animal species can tolerate for a major portion of its lifetime without significant impairment or toxic effect other than carcinogenicity

**measure of effect/measurement end point** a measurable characteristic of an ecological entity that can be related to an assessment end point (e.g., a laboratory test for eight species meeting certain requirements may serve as a measure of effect for an assessment end point, such as survival of fish, aquatic, invertebrate, or algal species under acute exposure)

**measure of exposure** a measurable characteristic of a stressor (such as the specific amount of mercury in a body of water) used to help quantify the exposure of an ecological entity or individual organism

**mechanical aeration** use of a mechanical device to inject air into water to cause a waste stream to absorb oxygen

**mechanical separation** using mechanical means to separate waste into various components

**mechanical turbulence** random irregularities of fluid motion in air caused by buildings or other nonthermal processes

**media** air, water, sediment, rock, or soil, the subject of regulatory concern and activities

**medical surveillance** a periodic comprehensive review of a worker's health status; acceptable elements of such surveillance program are listed in the Occupational Safety and Health Administration standards for asbestos

**medical waste** any solid waste generated in the diagnosis, treatment, or immunization of human beings or animals, in medical research, or in the production or testing of biological materials

**medium-size water system** a water system that serves 3,300–50,000 customers

**mesotrophic** reservoirs and lakes that contain moderate quantities of nutrients and are moderately productive in terms of aquatic animal and plant life

**metabolites** any substances produced by biological processes, such as those from pesticides

**metalimnion** the middle layer of a thermally stratified lake or reservoir. In this layer, there is a rapid decrease in temperature with depth. Also called thermocline

**methane** a colorless, nonpoisonous, flammable gas created by anaerobic decomposition of organic compounds. A major component of natural gas used in the home

**methanol** an alcohol that can be used as an alternative fuel or as a gasoline additive. It is less volatile than gasoline; blended with gasoline, it lowers the carbon monoxide emissions but increases hydrocarbon emissions. Used as pure fuel, it produces emissions that are less ozone-forming than those from gasoline. Poisonous to humans and animals if ingested

**methyl orange alkalinity** a measure of the total alkalinity in a water sample in which the color of methyl orange reflects the change in level

**microbial growth** the amplification or multiplication of microorganisms such as bacteria, algae, diatoms, plankton, and fungi

**microbial pesticide** a microorganism that is used to kill a pest but has minimal toxicity to humans

**microclimate** localized climate conditions within an urban area or neighborhood. Also, the climate around a tree or shrub or a stand of trees

**microenvironmental method** a method for sequentially assessing exposure for a series of microenvironments that can be approximated by constant concentrations of a stressor

**microenvironments** well-defined surroundings such as the home, office, or kitchen that can be treated as uniform in terms of stressor concentration

**mineral reserve** the proven amount of ore in the ground that can be recovered under current economic conditions

**minimization** a comprehensive program to minimize or eliminate wastes, usually applied to wastes at their point of origin

**mining of an aquifer (water mining)** withdrawal over a period of groundwater that exceeds the rate of recharge of the aquifer

- mining waste** residues resulting from the extraction of raw materials from the earth
- minors** publicly owned treatment works with flows less than 1 million gallons (3.8 million L) per day
- minor source** new emissions sources or modifications to existing emissions sources that do not exceed NAAQS emission levels
- miscellaneous ACM** interior asbestos-containing building material or structural components, members, or fixtures, such as floor and ceiling tiles; does not include surfacing materials or thermal system insulation
- miscible liquids** two or more liquids that can be mixed and remain mixed under normal conditions
- missed detection** the situation that occurs when a test indicates that a storage tank is not leaking when it is
- mist** liquid particles measuring 40–500 micrometers ( $\mu\text{m}$ ), formed by condensation of vapor. By comparison, fog particles are smaller than 40  $\mu\text{m}$
- mitigation** measures taken to reduce adverse impacts on the environment
- mixed funding** settlements in which potentially responsible parties (PRPs) and the EPA share the cost of a remedial action
- mixed metals** recovered metals not sorted into categories such as aluminum, tin, or steel cans or ferrous or nonferrous metals
- mixed municipal waste** solid waste that has not been sorted into specific categories (such as plastic, glass, yard trimmings, etc.)
- mobile incinerator systems** hazardous waste incinerators that can be transported from one site to another
- mobile source** any nonstationary source of air pollution such as cars, trucks, motorcycles, buses, airplanes, and locomotives
- modified bin method** a method to calculate the required heating or cooling for a building based on how much energy the system would use if outdoor temperatures were within a certain interval and then multiplying the energy use by the time that the temperature interval typically occurs
- modified source** the enlargement of a major stationary pollutant source is often referred to as modification, implying that more emissions will occur
- moisture content** the amount of water lost from soil upon drying to a constant weight, expressed as the weight per unit of dry soil or as the volume of water per unit bulk volume of soil. For a fully saturated medium, moisture content indicates the porosity. Also, the water equivalent of snow on the ground; an indicator of snowmelt flood potential
- molten salt reactor** a thermal treatment unit that rapidly heats waste in a heat-conducting fluid bath of carbonate salt
- monitoring** periodic or continuous surveillance or testing to determine the level of compliance in various media or in humans, plants, and animals
- monitoring well** a well used to obtain water quality samples or measure groundwater levels. Also, a well drilled at a hazardous waste management facility or Superfund site to collect groundwater samples for the purpose of physical, chemical, or biological analysis to determine the amounts, types, and distribution of contaminants in the groundwater beneath the site
- monoclonal antibodies (also called MABs and MCAs)** clones of a molecule, produced in quantity for medical or research purposes. Also, molecules of living organisms that selectively attach to other molecules to which their structure conforms exactly. This also could apply to equivalent activity by chemical molecules
- monomictic** lakes and reservoirs that are relatively deep, do not freeze over during winter, and undergo a single stratification and mixing cycle during the year (usually in the fall)
- Montreal Protocol** a 1987 international treaty that governs stratospheric ozone protection, research, and production and use of ozone-depleting substances. It provides for the end of production of ozone-depleting substances such as CFCs. Under the protocol, a fund was established to assist developing nations in the transition to ozone-safe technologies
- monsoon** a continental weather system caused by uneven heating of land and sea in which winds blow landward and carry rain. In the winter, when the land is warmer than the ocean, the direction of the monsoon reverses, and the wind blows seaward
- moratorium** during the negotiation process, a period of 60–90 days during which the EPA and potentially responsible parties (PRPs) may reach a settlement but no site activities can be conducted
- morbidity** rate of disease incidence
- mortality** death rate
- most probable number** an estimate of microbial density per unit volume of water sample, based on probability theory
- muck soils** wet soil made from decaying plant materials
- mulch** a layer of material (wood chips, straw, leaves, etc.) placed around plants to hold moisture, prevent weed growth, and enrich or sterilize the soil

**multimedia approach** joint approach to the management of environmental media, such as air, water, and land

**multiple chemical sensitivity** a diagnostic label for people who suffer multisystem illnesses as a result of contact with, or proximity to, a variety of airborne agents and other substances

**municipal discharge** discharge of wastewater from treatment plants that process it from households, commercial establishments, and industries in the coastal drainage basin. Combined sewer/separate storm overflows are included in this category

**municipal sewage** wastes (mostly liquid) originating from a community; may be composed of domestic wastewaters and/or industrial discharges

**municipal sludge** semiliquid residue remaining from the treatment of municipal water and wastewater

**municipal solid waste** common garbage or trash generated by industries, businesses, institutions, and homes

**mutagen/mutagenicity** an agent that causes a permanent genetic change in a cell. Mutagenicity is the capacity of a chemical or physical agent to cause such permanent changes

**National Ambient Air Quality Standards (NAAQS)** standards established by the EPA that apply to outdoor air throughout the country

**National Emissions Standards for Hazardous Air Pollutants (NESHAPS)** emissions standards set by the EPA for an air pollutant not covered by NAAQS that may cause an increase in fatalities or serious, irreversible, or incapacitating illness. Primary standards are designed to protect human health, secondary standards to protect public welfare (e.g., building facades, visibility, crops, and domestic animals)

**National Oil and Hazardous Substances Contingency Plan (NOHSCP/NCP)** the federal regulation that guides determination of the sites to be corrected under both the Superfund program and the program to prevent or control spills into surface waters or elsewhere

**National Pollutant Discharge Elimination System (NPDES)** a provision of the Clean Water Act that prohibits discharge of pollutants into waters of the United States unless a special permit is issued by the EPA, a state, or, where delegated, a tribal government on an Indian reservation

**National Priorities List (NPL)** the EPA's list of the most serious uncontrolled or abandoned hazardous waste sites identified for possible long-term remedial action under Superfund. The list is based primarily on the score a site receives

from the Hazard Ranking System. The EPA is required to update the NPL at least once a year. A site must be on the NPL to receive money from the trust fund for remedial action

**National Response Center** the federal operations center that receives notifications of all releases of oil and hazardous substances into the environment; open 24 hours a day, operated by the U.S. Coast Guard, which evaluates all reports and notifies the appropriate agency

**National Response Team (NRT)** representatives of 13 federal agencies that, as a team, coordinate federal responses to nationally significant incidents of pollution (an oil spill, a major chemical release, or a Superfund response action) and provide advice and technical assistance to the responding agency(ies) before and during a response

**natural gas** a fossil fuel composed primarily of methane created as a by-product when bacteria decompose organic material under anaerobic conditions

**navigable waters** streams and rivers sufficiently deep and wide for navigation by all or specified vessels; such waters in the United States are under federal jurisdiction and are protected by certain provisions of the Clean Water Act

**necrosis** death of plant or animal cells or tissues. In plants, necrosis can discolor stems or leaves or kill the plant

**nematicide** a chemical agent that is destructive to nematodes

**nephelometric** method of measuring turbidity in a water sample by passing light through the sample and measuring the amount of the light that is deflected

**netting** a concept in which all emissions sources in the same area owned or controlled by a single company are treated as one large source, thereby allowing flexibility in controlling individual sources in order to meet a single emissions standard

**neutralization** decreasing the acidity or alkalinity of a substance by adding alkaline or acidic materials, respectively

**new source** any stationary source of air pollution built or modified after publication of final or proposed regulations

**New Source Performance Standards (NSPS)** uniform national EPA air emission and wastewater standards that limit the amount of pollution from new sources or from modified existing sources

**New Source Review (NSR)** a Clean Air Act requirement that state implementation plans

must include a permit review of the construction and operation of new and modified stationary pollution sources in nonattainment areas

**niche** the functional role of a species in an ecosystem

**nitrate** a compound containing nitrogen that can exist in the atmosphere or as a dissolved gas in water. Nitrates in water can cause severe illness in infants and domestic animals. A plant nutrient and inorganic fertilizer, nitrate is found in septic systems, animal feedlots, agricultural fertilizers, manure, industrial wastewaters, sanitary landfills, and garbage dumps

**nitrification** the process whereby ammonia in wastewater is oxidized to nitrite and then to nitrate by bacterial or chemical reactions

**nitritotriacetic acid (NTA)** a compound that replaces phosphates in detergents

**nitrite** an intermediate in the process of nitrification. Also, nitrous oxide salts used in food preservation

**nitrogen cycle** a major nutrient cycle that converts atmospheric nitrogen to bioavailable forms, eventually returning it to the atmosphere

**nitrogenous wastes** animal or vegetable residues that contain significant amounts of nitrogen

**nitrophenols** synthetic organopesticides containing carbon, hydrogen, nitrogen, and oxygen

**“no further remedial action planned”** determination made by the EPA after a preliminary assessment that a site does not pose a significant risk and so requires no further activity under CERCLA

**nonbiodegradable** a pollutant that is not destroyed in a reasonable amount of time by organisms that occur naturally in the soil or water

**nonrenewable resource** a resource that is in limited supply and formed much more slowly than it is used

**no observable adverse effect level (NOAEL)** an exposure level at which there is no statistically or biologically significant increase in the frequency or severity of adverse effects between the exposed population and its appropriate control; some effects may be produced at this level, but they are not considered as adverse or as precursors to adverse effects

**no-observed-effect-level (NOEL)** exposure level at which there are no statistically or biologically significant differences in the frequency or severity of any effect in the exposed or control populations

**nonaqueous phase liquid (NAPL)** contaminant that remains undiluted as the original bulk liquid in the subsurface (e.g. spilled oil)

**nonattainment area** an area that does not meet one or more of the National Ambient Air Quality Standards for the criteria pollutants designated in the Clean Air Act

**Non-Binding Allocations of Responsibility (NBAR)** a process for the EPA to propose a method for potentially responsible parties (PRPs) to allocate costs among themselves

**noncommunity water system** a public water system that is not a community water system (e.g., the water supply at a campsite or national park)

**noncompliance coal** any coal that emits more than three pounds (1.4 kg) of sulfur dioxide per million BTU when burned. Also known as high-sulfur coal

**noncontact cooling water** water used for cooling that does not have direct contact with any raw material, product, by-product, or waste

**nonconventional pollutant** any pollutant not statutorily listed or that is poorly understood by the scientific community

**nondegradation** an environmental policy that disallows any lowering of naturally occurring quality regardless of preestablished health standards

**nondischarging treatment plant** a treatment plant that does not discharge treated wastewater into any stream or river. Most are pond systems that dispose of the total flow they receive by means of evaporation or percolation to groundwater, or facilities that dispose of their waste water by recycling or reuse (e.g., spray irrigation or groundwater discharge)

**nonferrous metals** metals such as aluminum, lead, and copper that contain no iron. Products made all or in part from such metals include containers, packaging, appliances, furniture, electronic equipment, and aluminum foil

**nonfriable asbestos-containing material** any material containing more than 1 percent asbestos that cannot be crumbled, pulverized, or reduced to powder by hand pressure

**nonhazardous industrial waste** industrial waste in wastewater not considered municipal solid waste or hazardous waste under RARA

**nonionizing electromagnetic radiation** radiation that does not change the structure of atoms but does heat tissue and may cause harmful biological effects. Includes microwaves, radio waves, and low-frequency electromagnetic fields from high-voltage transmission lines

**nonmethane hydrocarbon (NMHC)** the sum of all hydrocarbon air pollutants except methane; significant precursors to ozone formation

- nonmethane organic gases (NMOG)** the sum of all organic air pollutants. Excluding methane, they account for aldehydes, ketones, alcohols, and other pollutants that are not hydrocarbons but are precursors of ozone
- nonpoint sources** diffuse pollution sources (i.e., without a single point of origin or not introduced into a receiving stream from a specific outlet). The pollutants generally are carried off the land by storm water
- nonpotable water** water that is unsafe or unpalatable to drink because it contains pollutants, contaminants, minerals, or infective agents
- nonroad emissions** pollutants emitted by combustion engines on farm and construction equipment, gasoline-powered lawn and garden equipment, and power boats and outboard motors
- nontransient noncommunity water system** a public water system that regularly serves at least 25 of the same nonresident persons per day for more than six months per year
- notice of deficiency** an EPA request to a facility owner or operator requesting additional information before a preliminary decision on a permit application can be made
- notice of intent to cancel** notification sent to registrants when the EPA decides to cancel registration of a product containing a pesticide
- notice of intent to deny** notification by the EPA of its preliminary intent to deny a permit application
- notice of intent to suspend** notification sent to a pesticide registrant when the EPA decides to suspend product sale and distribution because of failure to submit requested data in a timely and/or acceptable manner, or because of imminent hazard
- nuclear reactors and support facilities** uranium mills, commercial power reactors, fuel reprocessing plants, and uranium enrichment facilities
- nuclear winter** prediction by some scientists that smoke and debris rising from massive fires of a nuclear war could block sunlight for weeks or months, cooling the Earth's surface and producing climate changes that could, for example, negatively affect world agricultural and weather patterns
- nutrient** any substance assimilated by living things that promotes growth. The term is generally applied to nitrogen and phosphorus in wastewater but also is associated with other essential and trace elements
- nutrient pollution** contamination of water resources by excessive inputs of nutrients. In surface waters, excess algal production is a major concern
- ocean discharge waiver** a variance from Clean Water Act requirements for discharges into marine waters
- odor threshold** the minimal odor of a water or air sample that can be detected after successive dilutions with odorless water
- offsets** a concept whereby emissions from new or modified stationary sources are balanced by reductions from existing sources to stabilize total emissions
- off-site facility** a hazardous waste treatment, storage, or disposal area that is located away from the generating site
- offstream use** water withdrawn from surface water or groundwater sources for use at another place
- oil** a naturally occurring liquid composed of a complex mixture of hydrocarbons
- oil and gas waste** gas and oil drilling mud, oil production brines, and other waste associated with exploration for, development of, and production of crude oil or natural gas
- oil desulfurization** widely used precombustion method for reducing sulfur dioxide emissions from oil-burning power plants. The oil is treated with hydrogen, which removes some of the sulfur by forming hydrogen sulfide gas
- oil fingerprinting** a method that identifies sources and types of petroleum products and allows spills to be traced to their source
- oil shale** a kerogen-bearing sedimentary rock that yields liquid or gaseous hydrocarbons when heated
- oil trap** any geologic feature that accumulates oil or gas by preventing its upward movement
- oligotrophic lakes** deep, clear lakes with few nutrients, little organic matter, and a high dissolved-oxygen level
- on-scene coordinator (OSC)** the predesignated EPA, U.S. Coast Guard, or Department of Defense official who coordinates and directs Superfund removal actions or Clean Water Act oil or hazardous spill responses
- on-site facility** a hazardous waste treatment, storage, or disposal area that is located on the generating site
- open burning** uncontrolled fires in an open dump
- open dump** an uncovered site used for disposal of waste without environmental controls
- operable unit** term for each of a number of separate activities undertaken as part of a Superfund site cleanup. A typical operable unit would be removal of drums and tanks from the surface of a site

**operating conditions** conditions specified in a RCRA permit that dictate how an incinerator must operate as it burns different waste types. A trial burn is used to identify operating conditions needed to meet specified performance standards

**operation and maintenance** activities conducted after a Superfund site action is completed to ensure that the cleanup action is effective. Also, actions taken after construction to ensure that facilities to treat wastewater will be properly operated and maintained to achieve efficiency levels and wastewater limitations in an optimal manner. It can also be applied to an ongoing asbestos management plan in a school or other public building, including regular inspections, various methods of maintaining asbestos in place, and removal when necessary

**optimal corrosion control treatment** an erosion control treatment that minimizes the lead and copper concentrations at user's taps while also ensuring that the treatment does not violate any national primary drinking water regulations

**oral toxicity** ability of a pesticide or other chemical to cause injury when ingested

**ore** a natural material that is sufficiently enriched in one or more minerals to be mined profitably

**organic** referring to or derived from living organisms. In chemistry, any compound containing carbon and hydrogen

**organic matter** carbonaceous waste contained in plant or animal matter and originating from domestic or industrial sources

**organism** any form of animal or plant life

**organophosphates** pesticides that contain phosphorus

**organophyllic** a substance that readily combines with organic compounds

**organotins** chemical compounds used in antifouling paints to protect the hulls of boats and ships, buoys, and pilings from marine organisms such as barnacles

**original generation point** location where regulated medical or other material first becomes waste

**osmosis** the passage of a liquid from a weak solution to a more concentrated solution across a semipermeable membrane that allows passage of the solvent (water) but not the dissolved solids

**other ferrous metals** recyclable metals from strapping, furniture, and metal found in tires and consumer electronics but not metals found in construction materials or cars, locomotives, and ships

**other glass** recyclable glass from furniture, appliances, and consumer electronics. Does not

include glass from transportation products (cars, trucks, or shipping containers) and construction or demolition debris

**other nonferrous metals** recyclable nonferrous metals such as lead, copper, and zinc from appliances, consumer electronics, and nonpackaging aluminum products. Does not include nonferrous metals from industrial applications and construction and demolition debris

**other paper** for recyclable paper from books; third-class mail; commercial printing; paper towels, plates, and cups; and other nonpackaging paper such as posters, photographic papers, cards and games, milk cartons, folding boxes, bags, wrapping paper, and paperboard. Does not include wrapping paper or shipping cartons

**other plastics** recyclable plastic from appliances, eating utensils, plates, containers, toys, and various kinds of equipment. Does not include heavy-duty plastics such as yielding materials

**other solid waste** recyclable nonhazardous solid wastes, other than municipal solid waste, covered under Subtitle D of RARA

**other wood** recyclable wood from furniture, consumer electronics, cabinets, and other nonpackaging wood products. Does not include lumber and tree stumps recovered from construction and demolition activities and industrial process waste such as shavings and sawdust

**outdoor air supply** air drawn into a building from outside

**outfall** the place where effluent is discharged into receiving waters

**overdraft** the pumping of water from a groundwater basin or aquifer in excess of the supply flowing into the basin; results in a depletion, or "mining," of the groundwater in the basin

**overfire air** air forced into the top of an incinerator or boiler to fan the flames

**overflow rate** one of the guidelines for design of the settling tanks and clarifiers in a treatment plant; used by plant operators to determine whether tanks and clarifiers are over- or underused

**overgrazing** the consumption by too many animals of plant cover, impeding regrowth and slowing the replacement of sustainable biomass

**overland flow** a land application technique that cleanses wastewater by allowing it to flow over a sloped surface. As the water flows over the surface, contaminants are absorbed and the water is collected at the bottom of the slope for reuse

**overturn** one complete cycle of top-to-bottom mixing of previously stratified water masses. This phenomenon may occur in spring or fall or after

storms and results in uniformity of chemical and physical properties of water at all depths

**oxidation** the chemical addition of oxygen to break down pollutants or organic waste (e.g., destruction of chemicals such as cyanides, phenols, and organic sulfur compounds in sewage by bacterial and chemical means). The loss of electrons by an element, compound, or ion

**oxidation pond** an artificial (anthropogenic) body of water in which waste is consumed by bacteria, used most frequently with other waste-treatment processes

**oxidation-reduction potential** the electric potential required to transfer electrons from one compound or element (the oxidant) to another compound (the reducer)

**oxygenated fuels** gasoline that has been blended with alcohols or ethers that contain oxygen in order to reduce carbon monoxide and other emissions

**oxygenated solvent** an organic solvent containing oxygen as part of the molecular structure. Alcohols and ketones are oxygenated compounds often used as paint solvents

**ozonation/ozonator** application of ozone to water for disinfection or for taste and odor control. The ozonator is the device that does this

**ozone depletion** destruction of the stratospheric ozone layer that shields the earth from ultraviolet radiation harmful to life. This destruction of ozone is caused by the breakdown of certain chlorine- and/or bromine-containing compounds (chlorofluorocarbons or halons), which break down when they reach the stratosphere and then catalytically destroy ozone molecules

**ozone hole** a thinning break in the stratospheric ozone layer. Designation of the amount of such depletion as an "ozone hole" is made when the detected amount of depletion exceeds 50 percent. Seasonal ozone holes have been observed over both the Antarctic and Arctic regions, part of Canada, and the extreme northeastern United States

**ozone layer** the protective layer in the atmosphere, about 15 miles (24 km) above the ground, that absorbs some of the Sun's ultraviolet rays, thereby reducing the amount of potentially harmful radiation that reaches the Earth's surface

**packed bed scrubber** an air pollution control device in which emissions pass through alkaline water to neutralize hydrogen chloride gas

**packed tower** a pollution control device that forces dirty air through a tower packed with crushed rock or wood chips while liquid is sprayed over the packing material. The pollut-

ants in the airstream either dissolve or chemically react with the liquid

**packer** an inflatable gland, or balloon, used to create a temporary seal in a borehole, probe hole, well, or drive casing. It is made of rubber or nonreactive materials

**paper processor/plastics processor** factory or plant where recovered paper or plastic products and materials are sorted, decontaminated, and prepared for final recycling

**paraquat** a standard herbicide used to kill various types of crops, including marijuana. Causes lung damage if smoke from the crop is inhaled

**parasite** an organism that depends upon another for nourishment or some other benefit while causing harm to it

**Parshall flume** device used to measure the flow of water in an open channel

**particle count** results of a microscopic examination of treated water with a special particle counter that classifies suspended particles by number and size

**particulate loading** the mass of particulates per unit volume of air or water

**partition coefficient** measure of the sorption phenomenon, whereby a pesticide is divided between the soil and water phases; also referred to as adsorption partition coefficient

**passive smoking/secondhand smoke** inhalation of tobacco smoke produced by others

**passive treatment walls** technology in which a chemical reaction takes place when contaminated groundwater has contact with a barrier such as limestone or a wall containing iron filings

**pathogens** microorganisms (e.g., bacteria, viruses, or parasites) that can cause disease in humans, animals, and plants

**pathway** the physical course a chemical or pollutant takes from its source to the exposed organism

**peak electricity demand** the maximal electricity used to meet the cooling load of a building or buildings in a given area

**peak levels** levels of airborne pollutant contaminants much higher than average or occurring for short periods in response to sudden releases

**percent saturation** the amount of a substance that is dissolved in a solution compared to the amount that could be dissolved in it

**perched water** zone of unpressurized water held above the water table by impermeable rock or sediment

**percolating water** water that passes through rocks or soil under the force of gravity

**percolation** the movement of water downward through subsurface soil layers until the water table is reached. Under certain conditions also can involve the upward movement of water. This term is sometimes applied to the slow seepage of water through a filter

**performance bond** cash or securities deposited before a landfill operating permit is issued, which are held to ensure that all requirements for operating and subsequently closing the landfill are performed. The money is returned to the owner (bond is released) after proper closure of the landfill is finished. If contamination or other problems appear at any time during operation or upon closure and are not addressed, the owner must forfeit all or part of the bond, which is then used to pay for cleanup costs

**performance data (for incinerators)** information collected during a trial burn on concentrations of designated organic compounds and pollutants found in incinerator emissions. Data analysis must show that the incinerator meets performance standards under operating conditions specified in its permit

**performance standards** regulatory requirements limiting the concentrations of designated organic compounds, particulate matter, and hydrogen chloride in emissions from incinerators. Also, operating standards established by the EPA for various permitted pollution control systems, asbestos inspections, and various program operations and maintenance requirements

**periphyton** microscopic underwater plants and animals that are firmly attached to solid surfaces such as rocks, logs, and pilings

**permeability** the rate at which liquids pass through soil or other materials

**permissible dose** the dose of a chemical that may be received by an individual without the expectation of a significantly harmful result

**permissible exposure limit (PEL)** federal limit for workplace exposure to contaminants as established by OSHA

**permit** an authorization, license, or equivalent control document issued by the EPA or an approved state agency to implement the requirements of an environmental regulation (e.g., a permit to operate a wastewater treatment plant or to operate a facility that may generate harmful emissions)

**persistence** the length of time a compound stays in the environment

**persistent bioaccumulative toxic chemical** a nonbiodegradable toxin that is released into and accumulates in the environment

**persistent pesticides** pesticides that do not break down chemically or only break down very slowly and remain in the environment after a growing season

**personal air samples** air samples taken with a pump that is directly attached to a worker with the collecting filter and cassette placed in the worker's breathing zone; required under OSHA asbestos standards and the EPA worker protection rule

**personal measurement** a measurement collected from an individual's immediate environment

**personal protective equipment** clothing and equipment worn by pesticide mixers, loaders and applicators and reentry workers, hazmat emergency responders, workers cleaning up Superfund sites, and others to reduce their exposure to potentially hazardous chemicals and other pollutants

**pest** an insect, rodent, nematode, fungus, weed, or other form of terrestrial or aquatic plant or animal life that is injurious to health or the environment

**pest control operator** person or company that applies pesticides as a business (e.g., exterminator); usually describes household services, not agricultural applications

**pesticide** substance or mixture of pesticides intended for preventing, destroying, repelling, or mitigating any pest. Also, any substance or mixture developed for use as a plant regulator, defoliant, or desiccant

**Pesticide Regulation Notice** formal notice to pesticide registrants about important changes in regulatory policy, procedures, and regulations

**pesticide tolerance** the amount of pesticide residue allowed by law to remain in or on a harvested crop. The EPA sets these levels below the amount where the compounds might be harmful to consumers

**petroleum** crude oil or its components that are liquid under normal conditions of temperature and pressure. The term includes petroleum-based substances comprising a complex blend of hydrocarbons derived from crude oil through the process of separation, conversion, upgrading, and finishing, such as motor fuel, jet oil, lubricants, petroleum solvents, and used oil

**petroleum derivatives** chemicals formed when gasoline breaks down in contact with groundwater

**pH (power of hydrogen)** a quantity that measures the degree of the basic or acid condition of a liquid. The pH typically ranges from 0 to 14, where 7 is neutral; less than 7 is acidic and greater than 7 is basic. Natural waters typically have a pH between 6.5 and 8.5

**pharmacokinetics** the study of the way that drugs move through the body after they are inhaled, absorbed through the skin, swallowed, or injected

**phenolphthalein alkalinity** the alkalinity in a water sample measured by the amount of standard acid needed to lower the pH to a level of 8.3 as indicated by the change of color of the indicator chemical (phenolphthalein) from pink to clear

**phenols** organic compounds that are by-products of petroleum refining, tanning, and textile, dye, and resin manufacturing. Low concentrations cause taste and odor problems in water; higher concentrations can kill aquatic life and humans

**phosphates** chemical compounds containing phosphorus

**phosphogypsum piles (stacks)** by-products generated during the production of phosphoric acid from phosphate rock

**phosphorus plants** facilities using electric furnaces to produce elemental phosphorus for commercial use, such as high-grade phosphoric acid, phosphate-based detergent, and organic chemicals use

**photochemical oxidants** air pollutants formed by the action of sunlight on oxides of nitrogen and hydrocarbons

**photochemical smog** air pollution caused by chemical reactions of sunlight and various pollutants emitted from different sources

**photosynthesis** the manufacture by plants of carbohydrates and oxygen from carbon dioxide mediated by chlorophyll in the presence of sunlight

**physical and chemical treatment** processes generally used in large-scale wastewater treatment facilities. Physical processes may include air-stripping or filtration. Chemical treatment includes coagulation, chlorination, or ozonation. The term also can refer to treatment of toxic materials in surface water and groundwater, oil spills, and some methods of addressing hazardous materials on or in the ground

**phytoplankton** that portion of the plankton community that comprises tiny autotrophic plants (e.g., algae, diatoms). They form the base of the food chain for aquatic animals

**phytoremediation** the use of plants and trees to remove or neutralize contaminants, as in polluted soil or water. It is a low-cost remediation option for sites with widely dispersed contamination at low concentrations

**phytotreatment** the cultivation of specialized plants that absorb specific contaminants from the soil through their roots or foliage. This pro-

cess reduces the concentration of contaminants in the soil but incorporates them into biomasses that may be released back into the environment when the plant dies or is harvested

**piezometer** a nonpumping well, generally of small diameter, for measuring the elevation (but not sampling) of the water table

**pilot test** preliminary or initial small-scale evaluation of a cleanup technology under actual site conditions to identify potential problems prior to full-scale implementation

**plankton** tiny plants and animals that live in water

**plasma arc reactors** devices that use an electric arc to decompose organic and inorganic materials thermally at ultrahigh temperatures into gases and a vitrified slag residue

**plasmid** a circular piece of DNA that exists apart from the chromosome and replicates independently of it. Bacterial plasmids carry information that renders the bacteria resistant to antibiotics. Plasmids often are used in genetic engineering to insert desired genes into organisms

**plate tower scrubber** an air pollution control device that neutralizes hydrogen chloride gas by bubbling alkaline water through it via holes in a series of metal plates

**plug flow** type of flow that occurs in tanks, basins, or reactors when a concentrated volume (slug) of water moves through without dispersing or mixing with the rest of the water flowing through

**plugging** act or process of stopping the flow of water, oil, or gas into or out of a formation through a borehole or well

**plume** a visible or measurable discharge of a contaminant from a given point of origin. Also, the area of radiation leaking from a damaged reactor. In hydrogeology, the three-dimensional shape a contaminant mass assumes within an aquifer after a release to the groundwater

**plutonium** a radioactive metallic element chemically similar to uranium

**PM10/PM2.5** PM10 is measure of particles in the atmosphere with a diameter of less than or equal to a nominal 10 micrometers. PM2.5 is a measure of particles in the air that are smaller than or equal to 2.5 micrometers. PM10 has been the pollutant particulate level standard against which the EPA has been measuring Clean Air Act compliance. On the basis of newer scientific findings, the agency is considering regulations that will make PM2.5 the new measurement standard

**pneumoconiosis** health conditions characterized by permanent deposition of substantial amounts of particulate matter in the lungs and by the tissue reaction to its presence; can range from

relatively harmless forms of sclerosis to the destructive fibrotic effect of silicosis

**point-of-contact measurement of exposure** estimating exposure by measuring concentrations over time (while the exposure is taking place) at or near the place where it is occurring

**point-of-disinfectant application** the place where disinfectant is applied and water downstream of that point is not subject to recontamination by surface water runoff

**point-of-use treatment device** a treatment device applied to a single tap or outlet to reduce contaminants in the drinking water

**point source** a stationary location or fixed facility from which pollutants are discharged; any single identifiable source of pollution (e.g., a pipe, ditch, ship, ore pit, factory smokestack)

**polar bond** a covalent bond in which the bonding electrons are not equally shared by the two atoms. Polar compounds generally are soluble in water

**pollen** the fertilizing element of flowering plants that also forms a background air pollutant

**pollutant** any substance introduced into the environment that adversely affects the usefulness of a resource or the health of humans, animals, or ecosystems

**pollutant pathways** avenues for distribution of pollutants. In most buildings, for example, HVAC systems are the primary pathways, but all building components can interact to affect air movement

**Pollutant Standard Index (PSI)** indicator of one or more pollutants that may be used to inform the public about the potential for adverse health effects from air pollution in major cities

**pollution** generally, the presence of a substance in the environment that, because of its chemical composition or quantity, prevents the functioning of natural processes and produces undesirable environmental and health effects. Under the Clean Water Act, for example, the term has been defined as the artificial alteration of the physical, biological, chemical, and radiological integrity of water and other media

**pollution prevention** identifying areas, processes, and activities that create excessive waste products or pollutants in order to reduce or prevent them by altering or eliminating a process

**polonium** a radioactive element that occurs in pitchblende and other uranium-containing ores

**polyelectrolytes** synthetic chemicals that help solids to clump during sewage treatment

**polyethylene terephthalate (PETE)** thermoplastic material used in plastic soft drink and rigid containers

**polymer** a natural or synthetic chemical structure where two or more similar molecules are joined to form a more complex molecular structure (e.g., polyethylene in plastic)

**population** a group of interbreeding organisms occupying a particular space. Also, the number of humans or other living creatures in a designated area

**population at risk** a population subgroup that is more likely to be exposed to a chemical or is more sensitive to the chemical than is the general population

**porosity** the amount of open or pore space in soil, gravel, sediment, or rock. Percentage of open spaces within a solid

**portal-of-entry effect** a local effect produced in the tissue or organ of first contact between a toxicant and the biological system

**postchlorination** addition of chlorine to wastewater for disinfectant purposes after it has been treated

**postclosure** the period after the shutdown of a waste management or manufacturing facility; for monitoring purposes, often considered to be 30 years

**postconsumer materials/waste** materials or finished products that have served their intended use and have been diverted or recovered from waste destined for disposal. Postconsumer materials are part of the broader category of recovered materials

**postconsumer recycling** use of materials generated from residential and consumer waste for new or similar purposes (e.g., converting wastepaper from offices into corrugated boxes or newsprint)

**potable water** water that is safe for drinking, bathing, and cooking

**potential dose** the amount of a compound contained in material swallowed, breathed, or applied to the skin

**potentially responsible party (PRP)** any individual or company, including owners, operators, transporters, or generators, that may be responsible for or contributed to a spill or other contamination at a Superfund site. Whenever possible, through administrative and legal actions, the EPA requires PRPs to clean up hazardous sites they have contaminated

**potentiation** the ability of one chemical to increase the effect of another chemical

**potentiometric surface** the surface to which water in an aquifer will rise under hydrostatic pressure (the water table)

**precautionary principle** when information about potential risks is incomplete, basing decisions

about the best ways to manage or reduce risks on a preference for avoiding unnecessary health risks instead of on unnecessary economic expenditures

**prechlorination** the addition of chlorine at the beginning of the treatment process. Done mainly to disinfect and control tastes, odors, and aquatic growths, and to aid in coagulation and settling

**precipitate** a substance separated from a solution or suspension by chemical or physical change

**precipitation** removal of hazardous solids from liquid waste to permit safe disposal; removal of particles from airborne emissions as in rain (e.g., acid precipitation)

**precipitator** pollution control device that collects particles from an airstream

**precision** agreement among repeated measurements

**preconsumer materials/waste** materials generated in manufacturing and converting processes such as scrap, trimmings, and cuttings. Includes print overruns, overissue publications, and obsolete inventories

**precursor** in photochemistry, a compound antecedent to a pollutant. For example, volatile organic compounds (VOCs) and nitrogen oxides react in sunlight to form ozone or other photochemical oxidants. As such, VOCs and nitrogen oxides are precursors

**preharvest interval** the time between the last pesticide application and harvest of the treated crops

**preliminary assessment** the process of collecting and reviewing available information about a known or suspected waste site or release

**pressed wood products** materials used in building and furniture construction that are made from wood veneers, particles, or fibers bonded together with an adhesive applied under heat and pressure

**pressure sewers** a system of pipes in which water, wastewater, or other liquid is pumped to a higher elevation

**pretreatment** processes used by industries to reduce, eliminate, or alter the nature of wastewater pollutants from nondomestic sources before they are discharged into publicly owned treatment works

**prevalent levels** levels of airborne contaminant occurring under normal conditions

**prevalent level samples** air samples taken under normal conditions (also known as ambient background samples)

**Prevention of Significant Deterioration (PSD)** an EPA program in which state and/or federal permits are required in order to restrict emissions from new or modified sources in places where air

quality already meets or exceeds primary and secondary ambient air quality standards

**primacy** having the primary responsibility for administering and enforcing regulations

**primary effect** an effect in which the stressor acts directly on the ecological component of interest, not on other parts of the ecosystem

**primary standards** national ambient air quality standards designed to protect human health with an adequate margin for safety

**primary treatment** first stage of wastewater treatment in which solids are removed by screening and settling

**primary waste treatment** initial steps in wastewater treatment; screens and sedimentation tanks are used to remove most materials that float or settle. Primary treatment removes about 30 percent of carbonaceous biochemical oxygen demand (BOD) from domestic sewage

**Principal Organic Hazardous Constituents (POHCs)** hazardous compounds monitored during an incinerator's trial burn, selected for high concentration in the waste feed and difficulty of combustion

**prions** microscopic particles made of protein that can cause disease

**prior appropriation** a doctrine of water law that allocates the rights to use water on a first-come, first-served basis

**probability of detection** the likelihood, expressed as a percentage, that a test method will correctly identify a leaking tank

**process variable** a physical or chemical quantity that is monitored and controlled in the operation of a water treatment plant or industrial plant

**process verification** verifying that raw materials, water usage, waste treatment methods, production rate, and other factors of quantity and quality of pollutants contained in discharges are described in the permit application and issued permit

**process wastewater** water that has contact with any raw material, product, by-product, or waste

**process weight** total weight of all materials, including fuel, used in a manufacturing process; used to calculate the allowable particulate emission rate

**producers (primary producers)** plants that perform photosynthesis and provide food to consumers

**product** in chemistry, a substance that is formed in a chemical reaction. In manufacturing, the materials used or the finished goods that are available for sale

**product level** a measure of the amount of a product in a storage tank

**products of incomplete combustion (PICs)**

organic compounds formed by combustion. Usually generated in small amounts and sometimes toxic, PICs are heat-altered versions of the original material fed into the incinerator (e.g., charcoal is a PIC from burning wood)

**product water** water that has passed through a water treatment plant and is ready to be delivered to consumers

**proportionate mortality ratio (PMR)** the number of deaths from a specific cause in a specific period per 100 deaths from all causes during the same period

**proposed plan** a plan for a site cleanup that is available to the public for comment

**proteins** complex nitrogenous organic compounds of high molecular weight made of amino acids; essential for growth and repair of animal tissue

**protocol** a series of formal steps for conducting a test

**protoplast** a membrane-bound cell from which the outer wall has been partially or completely removed. The term often is applied to plant cells

**protozoa** one-celled animals that are larger and more complex than bacteria. May cause disease

**public comment period** the time allowed for the public to express its views and concerns regarding an action by the EPA

**public health approach** regulatory and voluntary focus on effective and feasible risk management actions at the national and community levels to reduce human exposures and risks, with priority given to reducing exposures with the greatest impacts in terms of the number of people affected and severity of the effect

**public health context** the incidence, prevalence, and severity of diseases in communities or populations and the factors that account for them, including infections, exposure to pollutants, and other exposures or activities

**public hearing** a formal meeting wherein EPA officials hear the public's views and concerns about an EPA action or proposal. The EPA is required to consider such comments when evaluating its actions. Public hearings must be held upon request during the public comment period

**publicly owned treatment works (POTWs)** a waste-treatment works owned by a state government, unit of local government, or Indian tribe and usually designed to treat domestic wastewaters

**public notice** notification by the EPA informing the public of actions such as the issuance of a draft permit or scheduling of a hearing. The EPA is required to ensure proper public notice,

including publication in newspapers and broadcast over radio and television stations

**public water system** a system that provides water for human consumption to at least 15 service connections or regularly serves 25 individuals

**pumping station** mechanical device installed in sewer or water system or other liquid-carrying pipelines to pump the liquids to a higher elevation

**pumping test** a test conducted to determine aquifer or well characteristics

**purging** removing stagnant air or water from a sampling zone or equipment prior to sample collection

**putrefaction** biological decomposition of organic matter associated with anaerobic conditions.

**putrescible** able to rot quickly enough to cause odors and attract flies

**pyrolysis** decomposition of a chemical by extreme heat

**qualitative data** information that cannot be easily described with numbers (e.g., feel, taste, image, reputation)

**qualitative use assessment** report summarizing the major uses of a pesticide including percentage of crop treated and amount of pesticide used on a site

**quality assurance/quality control** a system of procedures, checks, audits, and corrective actions to ensure that research, design, performance, environmental monitoring and sampling, and other technical and reporting activities are of the highest achievable quality

**quantitative data** information that can be easily expressed using numbers (e.g., size, mass, temperature)

**quench tank** a water-filled tank used to cool incinerator residues or hot materials during industrial processes

**radiation standards** regulations that set maximal exposure limits for protection of the public from radioactive materials

**radioactive decay** spontaneous change in an atom by emission of charged particles (alpha or beta) and/or gamma rays; also known as radioactive disintegration and radioactivity

**radioisotopes** chemical variants of radioactive elements with potentially oncogenic, teratogenic, and mutagenic effects on the human body

**radionuclide** radioactive particle, anthropogenic or natural, with a definitive atomic weight. Can remain as a soil or water pollutant for long periods, depending upon half-life

**radius of influence** the radial distance from the center of a well or boring to the point where there is no lowering of the water table or potentiometric

surface (the edge of the cone of depression). Also, the radial distance from an extraction well that has adequate airflow for effective removal of contaminants when a vacuum is applied

**radius of vulnerability zone** the maximal distance from the point of release of an airborne hazardous substance in which the airborne concentration may reach the level of concern under specified weather conditions

**rainbow report** comprehensive document giving the status of all pesticides now or ever in registration or special reviews. Known as the "rainbow report because chapters are printed on different colors of paper

**rangeland** land used for grazing livestock

**rasp** a machine that grinds waste into a manageable material and helps prevent odor

**raw sewage** untreated wastewater and its contents

**raw water** intake water prior to any treatment or use

**reactant** a substance that is consumed in a chemical reaction

**reactivity** refers to those hazardous wastes that are normally unstable and readily undergo violent chemical change but do not explode

**reaeration** introduction of air into the lower layers of a reservoir. As the air bubbles form and rise, the oxygen dissolves into the water and increases the dissolved oxygen concentration. The rising bubbles also move deeper water to the surface, where it absorbs oxygen from the atmosphere

**real-time monitoring** monitoring and measuring environmental conditions with technology and communication systems that provide current data

**reasonable maximum exposure** the maximal exposure reasonably expected to occur in a population

**reasonable worst case** an estimate of the individual dose, exposure, or risk level received by an individual in a defined population that is greater than the 90th percentile but less than that received by anyone in the 98th percentile in the same population

**Reasonably Available Control Measure (RACM)** a broadly defined term referring to technological and other measures for pollution control

**Reasonably Available Control Technology (RACT)** control technology that is reasonably available and both technologically and economically feasible. Usually applied to existing sources or air pollution in nonattainment areas

**recarbonization** process in which carbon dioxide is bubbled into water being treated to lower the pH

**receiving waters** a river, lake, ocean, stream, or other watercourse into which wastewater or treated effluent is discharged

**receptor** ecological entity exposed to a stressor

**recharge** the process by which water is added to a zone of saturation, usually by percolation from the soil surface (e.g., the recharge of an aquifer)

**recharge area (or zone)** a land area in which water reaches the zone of saturation from surface infiltration (e.g., where rainwater soaks through the soil and enters an aquifer)

**recharge rate** the quantity of water per unit of time that replenishes or refills an aquifer

**reclamation** restoration of materials found in the waste stream to some beneficial use. In mining, placement of fill (usually tailings and spoils) and reestablishment of vegetation to restore functioning ecology to an area where minerals have been extracted

**recombinant bacteria** a microorganism whose genetic makeup has been altered by deliberate introduction of new genetic elements. The offspring of these altered bacteria also contain these new genetic elements

**recombinant DNA** the new DNA that is formed by combining pieces of DNA from different organisms or cells

**Recommended Maximum Contaminant Level (RMCL)** the maximal level of a contaminant in drinking water at which no known or anticipated adverse effect on human health would occur and that includes an adequate margin of safety

**reconstruction of dose** estimating exposure after it has occurred by using evidence within an organism such as chemical levels in tissue or fluids

**Record of Decision (ROD)** a public document that explains which cleanup alternative(s) will be used at National Priorities List sites where CERCLA trust funds pay for the cleanup

**recovery rate** percentage of usable recycled materials that have been removed from the total amount of municipal solid waste generated in a specific area or by a specific business

**recycle/reuse** minimizing waste generation by recovering and reprocessing usable products that might otherwise become waste (recycling of aluminum cans, paper, and bottles, etc.)

**recycling mill** facility where recovered materials are remanufactured into new products

**redemption program** a program in which consumers are compensated for collection of recyclable materials, generally through prepaid deposits or taxes on beverage containers. In some states or localities legislation has enacted redemption programs to help prevent roadside litter

**red list** a list of species at an unusually high level of risk for extinction

**red tide** a proliferation of a marine plankton that are toxic to fish, perhaps stimulated by the addition of nutrients. A tide can be red, green, or brown, depending on the coloration of the plankton

**reduction** a chemical reaction that includes the addition of hydrogen, removal of oxygen, or addition of electrons to an element or compound

**reef** a wave-resistant ridge or mound built by corals or other marine invertebrate organisms

**reentry (in indoor air program)** refers to air exhausted from a building that is immediately drawn back into the system through the air intake and other openings

**reentry interval** the period immediately after the application of a pesticide during which unprotected workers should not enter a field

**reference dose (RfD)** a numerical estimate of a daily oral exposure to the human population, including sensitive subgroups such as children, that is not likely to cause harmful effects during a lifetime. RfDs are generally used for health effects that are thought to have a threshold or low dose limit for producing effects

**reflection** the bouncing and return or diversion of a wave that strikes a surface (interface)

**reformulated gasoline** gasoline with a different composition from conventional gasoline (i.e., lower aromatics content) that reduces air pollutants

**refraction** the bending of a wave when it changes velocity as it passes from one medium to another

**refueling emissions** emissions released during vehicle refueling

**refuse reclamation** conversion of solid waste into useful products (e.g., composting organic wastes to make soil conditioners or separating aluminum and other metals for recycling)

**Regional Response Team (RRT)** representatives of federal, local, and state agencies who may assist in coordination of activities at the request of the on-scene coordinator before and during a significant pollution incident such as an oil spill, major chemical release, or Superfund response.

**registrant** any manufacturer or formulator who obtains registration for a pesticide active ingredient or product

**registration** formal listing with the EPA of a new pesticide before it can be sold or distributed. Under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), the EPA is responsible for registration (premarket licensing) of pesticides on the basis of data demonstrating no

unreasonable adverse effects on human health or the environment when applied according to approved label directions.

**Regulated Asbestos-Containing Material (RACM)** friable asbestos containing material (ACM) or nonfriable ACM subjected to sanding, grinding, cutting, or abrading or that has crumbled or been pulverized or reduced to powder during demolition or renovation operations

**regulated medical waste** under the Medical Waste Tracking Act of 1988, any solid waste generated in the diagnosis, treatment, or immunization of human beings or animals, in medical research, or in the production or testing of biologicals. Included are cultures and stocks of infectious agents, human blood and blood products, human pathological body wastes from surgery and autopsy, contaminated animal carcasses from medical research, waste from patients who have communicable diseases, and all used sharp implements, such as needles and scalpels, and certain unused sharps

**relative ecological sustainability** ability of an ecosystem to maintain its ecological integrity indefinitely

**relative permeability** the permeability of a rock to gas, NAPL, or water, when any two or more are present

**release** any spilling, leaking, pumping, pouring, emitting, emptying, discharging, injecting, escaping, leaching, dumping, or disposing into the environment of a hazardous or toxic chemical or extremely hazardous substance

**remedial action (RA)** the actual construction or implementation phase of a Superfund site cleanup that follows remedial design

**remedial design** a phase of remedial action that follows the remedial investigation/feasibility study (RI/FS) and includes development of engineering drawings and specifications for a site cleanup

**remedial investigation** an in-depth study designed to gather data needed to determine the nature and extent of contamination at a Superfund site, establish site cleanup criteria, identify preliminary alternatives for remedial action, and support technical and cost analyses of alternatives. The remedial investigation is usually done with the feasibility study. Together they are usually referred to as the RI/FS

**Remedial Project Manager (RPM)** the EPA or state official responsible for overseeing on-site remedial action. Sometimes referred to as the case manager

**remedial response** long-term action that stops or substantially reduces a release or threat of a

release of hazardous substances that is not an immediate threat to public health

**remediation** cleanup or other methods used to remove or contain a toxic spill or hazardous materials from a Superfund site

**remote sensing** the collection and interpretation of information about an object without physical contact with the object (e.g., satellite imaging, aerial photography, and open path measurements)

**removal action** short-term immediate actions taken to address releases of hazardous substances that require expedited response

**renewable resource** a natural resource that is virtually unlimited or that is replenished by the environment over relatively short periods

**reportable quantity (RQ)** quantity of a hazardous substance that triggers a reporting requirement under CERCLA. If a substance exceeds its RQ, the release must be reported to the National Response Center and community emergency coordinators for areas likely to be affected

**repowering** rebuilding and replacing major components of a power plant instead of building a new one

**representative sample** a portion of material or liquid that is as nearly identical in content and consistency as possible to that in the larger body of material or liquid being sampled

**reserve capacity** extra treatment capacity built into solid waste and wastewater treatment plants and interceptor sewers to accommodate flow increases due to future population growth

**reservoir** any natural or artificial holding area used to store, regulate, or control water

**residential use** pesticide application in and around houses, office buildings, apartment buildings, motels, and other living or working areas

**residential waste** all waste generated in single and multifamily homes other than those that are diverted to backyard composting

**residual** amount of a pollutant remaining in the environment after a natural or technological removal process, for example, particulate remaining in air after it passes through a bag-house filter

**residual risk** the extent of health risk from air pollutants remaining after application of the Maximum Achievable Control Technology (MACT)

**residual saturation** saturation level below which fluid drainage does not occur

**residue** the dry solids remaining after the evaporation of a sample of water or sludge

**resistance** for plants and animals, the ability to withstand poor environmental conditions or attacks by chemicals or disease

**resource recovery** the process of obtaining matter or energy from formerly discarded materials

**response action** term for actions taken in response to actual or potential health-threatening environmental events such as spills, sudden releases, and asbestos abatement/management problems. Also, a CERCLA-authorized action involving either a short-term removal action or a long-term removal response. This may include but is not limited to removing hazardous materials from a site to an EPA-approved hazardous waste facility for treatment, containing or treating the waste on-site, identifying and removing the sources of groundwater contamination, and halting further migration of contaminants

**responsiveness summary** a summary of oral and/or written public comments received by the EPA during a comment period on key EPA documents and the EPA's response to those comments

**restoration** measures taken to restore a site to pre-violation conditions

**restricted entry interval** the time after a pesticide application during which entry into the treated area is restricted

**restricted use pesticide (RUP)** a pesticide may be classified (under FIFRA regulations) for restricted use if it requires special handling because of its toxicity, and, if so, it may be applied only by trained, certified applicators or those under their direct supervision

**restriction enzymes** enzymes that recognize specific regions of a long deoxyribonucleic acid (DNA) molecule and cut it at those points

**retrofit** addition of a pollution control device on an existing facility without making major changes to the generating plant. Also called backfit

**reuse** using a product or component of municipal solid waste in its original form more than once (e.g., refilling a glass bottle that has been returned or using a coffee can to hold nuts and bolts)

**reverse osmosis** a treatment process used in water systems that adds pressure to force water through a semipermeable membrane. Reverse osmosis removes most drinking water contaminants. Also used in wastewater treatment

**reversible effect** a health effect that is not permanent; especially an adverse effect that diminishes when exposure to a toxic chemical stops

**ribonucleic acid (RNA)** a molecule that carries the genetic message from deoxyribonucleic acid (DNA) to a cellular protein-producing mechanism

- rill** a small channel eroded into the soil by surface runoff; can be easily smoothed out or obliterated by normal tillage
- Ringelmann chart** a chart containing a scale of shades/screens used to measure the opacity of air pollution emissions, ranging from light gray through black; used to set and enforce emissions standards
- riparian habitat** areas adjacent to rivers and streams with a differing density, diversity, and productivity of plant and animal species relative to nearby uplands
- riparian rights** entitlement of a landowner to certain uses of water on or bordering the property, including the right to prevent diversion or misuse of upstream waters; generally a matter of state law
- risk** a measure of the probability that damage to life, health, property, and/or the environment will result from a given activity
- risk assessment** qualitative and quantitative evaluation of the risk posed to human health and/or the environment by the actual or potential presence and/or use of specific pollutants
- risk-based targeting** the direction of resources to those areas that have been identified as having the highest potential or actual adverse effect on human health and/or the environment
- risk characterization** the last phase of the risk assessment process that estimates the potential for adverse health or ecological effects from exposure to a stressor and evaluates the uncertainty involved
- risk communication** the exchange of information about health or environmental risks among risk assessors and managers, the general public, news media, interest groups, and others
- risk estimate** a description of the probability that organisms exposed to a specific dose of a chemical or other pollutant will develop an adverse response
- risk factor** characteristics (e.g., race, sex, age, obesity) or variables (e.g., smoking, occupational exposure level) associated with increased probability of a toxic effect
- risk management** the process of evaluating and selecting alternative regulatory and nonregulatory responses to risk. The selection process requires the consideration of legal, economic, and behavioral factors
- risk-specific dose** the dose associated with a specified risk level
- river basin** the land area drained by a river and its tributaries
- roasting** pretreatment of ore by heating to below its melting point, usually in the presence of air. This converts the ore into a chemical form more suitable for further processing
- rodenticide** a chemical or agent used to destroy rats or other rodent pests or to prevent them from damaging food, crops, and so on
- rotary kiln incinerator** an incinerator with a rotating combustion chamber that keeps waste moving, thereby allowing it to vaporize for easier burning
- route of exposure** the way a chemical has contact with an organism (e.g., inhalation, ingestion, dermal contact, injection)
- rubbish** solid waste, excluding food waste and ashes, from homes, institutions, and workplaces
- runoff** that part of precipitation, snowmelt, or irrigation water that flows over the land and enters streams or other surface water. It can sweep pollutants from the air and land into receiving waters
- sacrificial anode** an easily corroded material installed in a pipe or tank to prevent corrosion
- safe** condition of exposure under which there is a practical certainty that no harm to exposed individuals will result
- safener** a chemical added to a pesticide to prevent it from injuring plants
- safe yield** the annual amount of groundwater that can be taken from a source of supply (aquifer) over a period of years without depleting that source beyond its ability to be replenished naturally
- salinity** the percentage of salt in water
- salts** minerals made up of a cation from a base and an anion from an acid. Water picks up salt as it passes through the air, over and under the ground, or from households and industry
- salvage** the utilization of waste materials
- sampling frequency** the interval between the collections of successive samples
- sand filters** devices that remove some suspended solids from sewage. Air and bacteria decompose additional wastes filtering through the sand so that cleaner water drains from the filter
- sanitary sewers** underground pipes that carry away domestic or industrial waste but not storm water
- sanitary water (gray water)** water discharged from sinks, showers, kitchens, or other nonindustrial operations, but not from toilets
- sanitation** control of physical factors in the human environment that could harm development, health, or survival
- saprolite** a soft, clay-rich, thoroughly decomposed rock formed in place by chemical weathering of

rock. Forms in humid, tropical, or subtropical climates

**saprophytes** organisms living on dead or decaying organic matter that help natural decomposition of organic matter in water

**saturated zone** the area below the water table where all open spaces are filled with water

**saturation** the condition of a liquid when it has taken into solution the maximum possible quantity of a given substance at a given temperature and pressure

**Science Advisory Board (SAB)** a group of external scientists who advise the EPA on science and policy

**scrap** materials discarded from manufacturing operations that may be suitable for reprocessing.

**scrap metal processor** intermediate operating facility where recovered metal is sorted, cleaned of contaminants, and prepared for recycling

**screening** use of screens to remove coarse floating and suspended solids from sewage

**screening risk assessment** a risk assessment performed with few data and many assumptions to identify exposures that should be evaluated more carefully for potential risk

**scrubber** an air pollution device that uses a spray of water or reactant or a dry process to trap pollutants in emissions

**secondary drinking water regulations** nonenforceable regulations that apply to public water systems and specify the maximum contamination levels that, in the judgment of the EPA, are required to protect the public welfare. These regulations apply to any contaminants that may adversely affect the odor or appearance of water and consequently may cause people served by the system to discontinue its use

**secondary effect** action of a stressor on supporting components of the ecosystem, which, in turn, impact the ecological component of concern

**secondary extraction** the removal of additional crude oil by using solvents or by flushing underground rocks with water or steam

**secondary materials** materials that have been manufactured and used at least once and are to be used again

**secondary standards** national ambient air quality standards designed to protect welfare, including effects on soils, water, crops, vegetation, synthetic (anthropogenic) materials, animals, wildlife, weather, visibility, and climate; damage to property; transportation hazards; economic values; and personal comfort and well-being

**secondary treatment** the second step in most publicly owned waste treatment systems, in which bacteria consume the organic parts of the waste. It is accomplished by collecting together waste, bacteria, and oxygen in trickling filters or in the activated sludge process. This treatment removes floating and settleable solids and about 90 percent of the oxygen-demanding substances and suspended solids. Disinfection is the final stage of secondary treatment

**sedimentation** letting solids settle out of wastewater by gravity during treatment

**sedimentation tanks** wastewater tanks in which floating wastes are skimmed off and settled solids are removed for disposal

**sediments** soil, sand, and minerals washed from land into water, usually after rain. They pile up in reservoirs, rivers, and harbors, destroying fish and wildlife habitat and clouding the water so that sunlight cannot reach aquatic plants. Careless farming, mining, and building activities expose sediment materials, allowing them to wash off the land after precipitation

**sediment yield** the quantity of sediment arriving at a specific location

**seed protectant** a chemical applied before planting to protect seeds and seedlings from disease or insects

**seepage** percolation of water through the soil from unlined canals, ditches, laterals, watercourses, or water storage facilities

**selective pesticide** a chemical designed to affect only certain types of pests, leaving other plants and animals unharmed

**semiconfined aquifer** an aquifer partially confined by soil layers of low permeability through which recharge and discharge can still occur

**semipermeable membrane** thin films of materials that allow only water and other small molecules to pass through them. Examples include the skins of fruit and vegetables

**semivolatile organic compound (SVOC)** organic compound that volatilizes slowly at standard temperature and pressure (20°C and 1 atm pressure)

**senescence** the aging process. Sometimes used to describe lakes or other bodies of water in advanced stages of eutrophication. Also used to describe plants and animals

**septic system** an on-site system designed to treat and dispose of domestic sewage. A typical septic system consists of a tank that receives waste from a residence or business and a system of tile lines or a pit for disposal of the liquid effluent

- (sludge) that remains after decomposition of the solids by bacteria in the tank
- septic tank** an underground storage tank for wastes from homes not connected to a sewer line. Waste goes directly from the home to the tank
- service connector** the pipe that carries tap water from a public water main to a building
- service line sample** a 0.26-gallon (1-L) sample of water that has been standing for at least six hours in a service pipeline and is collected according to federal regulations
- service pipe** the pipeline extending from the water main to the building served or to the consumer's system
- settlable solids** material heavy enough to sink to the bottom of a wastewater treatment tank
- settling chamber** a series of screens placed in the way of flue gases to slow the stream of air, thus helping gravity to pull particles into a collection device
- settling tank** a holding area for wastewater, where heavier particles sink to the bottom for removal and disposal
- seven-day, consecutive low flow with a 10-year return frequency (7Q10)** the lowest stream flow for seven consecutive days that would be expected to occur once in 10 years
- sewage** the waste and wastewater produced by residential and commercial sources and discharged into sewers
- sewage sludge** sludge produced at a Publicly Owned Treatment Works, the disposal of which is regulated under the Clean Water Act
- sewer** a channel or conduit that carries wastewater and storm-water runoff from the source to a treatment plant or receiving stream. Sanitary sewers carry household, industrial, and commercial waste. Storm sewers carry runoff from rain or snow. Combined sewers handle both
- shading coefficient** the amount of the Sun's heat transmitted through a given window compared with that of a standard 1/8-inch-thick single pane of glass under the same conditions
- sharps** hypodermic needles, syringes (with or without the attached needle), Pasteur pipettes, scalpel blades, blood vials, needles with attached tubing, and culture dishes used in animal or human patient care or treatment or in medical, research, or industrial laboratories. Also included are other types of broken or unbroken glassware that had contact with infectious agents, such as used slides and coverslips and unused hypodermic and suture needles, syringes, and scalpel blades
- shelterbelt** a row of trees or other tall perennial vegetation placed along the edges of farm fields to slow wind speeds and reduce erosion
- shock load** the unanticipated arrival at a water treatment plant of raw water containing unusual amounts of algae, colloidal matter, suspended solids, turbidity, or other pollutants
- short-circuiting** occurs when some of the water in tanks or basins flows faster than the rest; may result in shorter contact, reaction, or settling times than calculated or presumed and not allow for adequate treatment
- sick building syndrome** condition of a building whose occupants experience acute health and/or comfort effects that appear to be linked to time spent therein, but where no specific illness or cause can be identified. Complaints may be localized in a particular room or zone or may spread throughout the building
- signal words** the words used on a pesticide label—*Danger*, *Warning*, *Caution*—to indicate level of toxicity
- significant deterioration** pollution resulting from a new source in previously uncontaminated areas
- significant municipal facilities** those publicly owned sewage treatment plants that discharge 1 million gallons (3.8 million L) per day or more and are therefore considered by states to have the potential to affect the quality of receiving waters substantially
- significant potential source of contamination** a facility or activity that stores, uses, or produces compounds with potential for significant contaminating impact if released into the source water of a public water supply
- significant violations** violations by point source dischargers of sufficient magnitude or duration to be a regulatory priority
- silt** sedimentary materials composed of fine-sized particles
- silviculture** management of forestland for timber
- single-breath canister** small 1-liter canister designed to capture a single breath. Used in air pollutant ingestion research
- sink** a place in the environment where a compound or material collects
- sinking** controlling oil spills by using an agent to trap the oil and force it to the bottom of the body of water, where the agent and the oil are biodegraded
- SIP Call** under the Clean Air Act, an EPA action requiring a state to resubmit all or part of its State Implementation Plan (SIP) to demonstrate

attainment of the required national ambient air quality standards within the statutory deadline

**site** an area or place within the jurisdiction of the EPA and/or a state where a release to the environment has or may have occurred

**Site Assessment Program** a means of evaluating hazardous waste sites through preliminary assessments and site inspections to develop a Hazard Ranking System score

**site inspection** the collection of information from a Superfund site to determine the extent and severity of hazards posed by the site. It follows and is more extensive than a preliminary assessment. The purpose is to gather information necessary to score the site, using the Hazard Ranking System, and to determine whether it presents an immediate threat requiring prompt removal

**siting** the process of choosing a location for a facility, usually involving extensive public input

**skimming** using a machine to remove floating oil or scum from the surface of the water

**slow sand filtration** passage of raw water through a bed of sand at low velocity, resulting in substantial removal of chemical and biological contaminants

**sludge** a semisolid residue from any of a number of air or water treatment processes; can be a hazardous waste

**sludge digester** tank in which complex organic substances such as sewage sludge are biologically dredged. During these reactions, energy is released and much of the sewage is converted to methane, carbon dioxide, and water

**slurry** a watery mixture of insoluble matter resulting from some pollution control techniques

**small-quantity generator (SQG);** sometimes referred to as Squeegee; persons or enterprises that produce 220–2,200 pounds (100–1,000 kg) per month of hazardous waste

**smelter** a facility that melts or fuses ore, often with accompanying chemical change, to separate its metal content. Emissions cause pollution

**smog** air pollution typically associated with oxidants

**smoke** particles suspended in air after incomplete combustion

**soft detergents** cleaning agents that biodegrade when released into the environment

**soft water** water that does not contain a significant amount of dissolved minerals such as salts of calcium or magnesium

**soil adsorption field** a subsurface area containing a trench or bed with clean stones and a system of piping through which treated sewage may seep into the surrounding soil for further treatment and disposal

**soil and water conservation practices** control measures consisting of managerial, vegetative, and structural practices to reduce the loss of soil and water

**soil conditioner** an organic material such as humus or compost that helps soil absorb water, build a bacterial community, and take up mineral nutrients

**soil erodibility** an indicator of a soil's susceptibility to raindrop impact, runoff, and other erosive processes

**soil gas** gaseous elements and compounds in the small spaces between particles of the earth and soil. Such gases can be moved or driven out under pressure

**soil moisture** the water contained in the pore space of soil in the unsaturated zone

**soil sterilant** a chemical that temporarily or permanently prevents the growth of all plants and animals

**solder** metallic compound used to seal joints between pipes. Until recently, most solder contained 50 percent lead. Use of solder containing more than 0.2 percent lead in pipes carrying drinking water is now prohibited

**sole-source aquifer** an aquifer that supplies 50 percent or more of the drinking water of an area

**solidification and stabilization** physical encapsulation or chemical alteration of a waste to make it less permeable and susceptible to transport by water

**solid waste** nonliquid, nonsoluble materials ranging from municipal garbage to industrial wastes that contain complex and sometimes hazardous substances. Solid wastes also include sewage sludge, agricultural refuse, demolition wastes, and mining residues. It also can include liquids and gases in containers

**solid waste disposal** the final placement of refuse that is not salvaged or recycled

**solid waste management** supervised handling of waste materials from their source through recovery processes to disposal

**solubility** the amount of mass of a compound that will dissolve in a unit volume of solution. Aqueous solubility is the maximal concentration of a chemical that will dissolve in pure water at a reference temperature

**solute** any substance being dissolved into a solution. Solutes are usually present in lesser quantities than the solvent

**solution** a homogeneous mixture of a solute in a carrying fluid (solvent) such as water

**solvent** the component of a solution that is present in the largest quantity. In aqueous systems, the solvent is water

**soot** carbon dust formed by incomplete combustion  
**sorption** the action of attracting substances by electrochemical means; process used in many pollution control systems

**source area** the location of liquid hydrocarbons or the zone of highest soil or groundwater concentrations of the chemical of concern

**source characterization measurements** measurements made to estimate the rate of release of pollutants into the environment from a source such as an incinerator or landfill

**source reduction** reducing the amount of materials entering the waste stream from a specific source by redesigning products or patterns of production or consumption (e.g., using returnable beverage containers)

**source separation** segregating various wastes at the point of generation (e.g., separation of paper, metal, and glass from other wastes to make recycling simpler and more efficient)

**sparge or sparging** injection of air below the water table to strip dissolved volatile organic compounds and/or oxygenate groundwater to facilitate aerobic biodegradation of organic compounds

**special waste** items such as household hazardous waste, bulky wastes (refrigerators, pieces of furniture, etc.), tires, and used oil

**species** a reproductively isolated aggregate of interbreeding organisms having common attributes and usually designated by a common name

**specific conductance** rapid method of estimating the dissolved solids content of a water supply by testing its capacity to carry an electrical current

**specific yield** the amount of water a unit volume of saturated permeable rock will yield when drained by gravity

**Spill Prevention, Containment, and Countermeasures Plan (SPCP)** plan describing actions to be taken in the event of a release of hazardous substances as defined in the Clean Water Act

**spoil** dirt or rock removed from its original location, destroying the composition of the soil in the process, as in strip-mining, dredging, or construction

**sprawl** unplanned development of open land

**spray tower scrubber** a device that sprays alkaline water into a chamber where acid gases are present to aid in neutralizing the gas

**spring** groundwater seeping out of the earth at a point where the water table intersects the ground surface

**spring melt/thaw** the process whereby warm temperatures melt winter snow and ice. Because various forms of acid deposition may have been stored

in the frozen water, the melt can result in the entry of abnormally large amounts of acidity into streams and rivers, sometimes causing fish kills

**stabilization** conversion of the active organic matter in sludge into inert, harmless material

**stabilization ponds** See LAGOON

**stable air** a motionless mass of air that retains, instead of dispersing, pollutants.

**stack** a chimney, smokestack, or vertical pipe that discharges used air

**stack effect** air, as in a chimney, that moves upward because it is warmer and consequently less dense than the ambient atmosphere. Also, the flow of air resulting from warm air rising, creating a positive pressure area at the top of a building and negative pressure area at the bottom. This effect can overpower the mechanical system and disrupt building ventilation and air circulation

**stack gas** See FLUE GAS

**Stage II Controls** systems placed on service station gasoline pumps to control and capture gasoline vapors during refueling

**stagnation** lack of motion in a mass of air or water that holds pollutants in place

**stakeholder** any organization, governmental entity, or individual that has an interest in or may be impacted by a given approach to environmental regulation, pollution prevention, energy conservation, or other action

**Standard Industrial Classification Code** also known as SIC Code, a method of grouping industries with similar products or services and assigning codes to these groups

**standards** norms that impose limits on the amount of pollutants or emissions produced. The EPA establishes minimal standards; states are allowed to be more strict

**standard sample** the part of finished drinking water that is examined for the presence of coliform bacteria

**State Implementation Plans (SIP)** EPA-approved state plans for the establishment, regulation, and enforcement of air pollution standards

**static water depth** the vertical distance from the centerline of the pump discharge down to the surface level of the well or standing water body. Measured while no water is being withdrawn from the water table

**static water level** elevation or level of the water table in a well when the pump is not operating. Also, the level or elevation to which water would rise in a tube connected to an artesian aquifer or basin in a conduit under pressure

**stationary source** a fixed-site producer of air pollution, mainly power plants and other facilities using industrial combustion processes

**sterilization** the removal or destruction of all microorganisms, including pathogenic and other bacteria, vegetative forms, and spores

**sterilizer** one of three groups of antimicrobials registered by the EPA for public health uses. The EPA considers an antimicrobial material to be a sterilizer if it destroys or eliminates all forms of bacteria, viruses, and fungi and their spores. Spores are considered the most difficult form of microorganism to destroy, and the EPA considers the term *sporicide* to be synonymous with *sterilizer*

**storage** temporary holding of waste pending treatment or disposal, as in containers, tanks, waste piles, and surface impoundments

**storm sewer** a system of pipes (separate from sanitary sewers) that carries water runoff from buildings and land surfaces

**stratigraphy** study of the formation, composition, and sequence of rocks and sediments, whether consolidated or not

**stratosphere** the portion of the atmosphere 10–25 miles (160–400 km) above the Earth's surface

**stressors** physical, chemical, or biological entities that can induce adverse effects on ecosystems or human health

**strip-cropping** growing crops in a systematic arrangement of strips or bands that serve as barriers to wind and water erosion

**strip-mining** a process that uses machines to scrape soil or rock away from mineral deposits just below the Earth's surface

**structural deformation** distortion in walls of a tank after liquid has been added or removed

**subchronic** of intermediate duration, usually used to describe studies or periods of exposure lasting between five and 90 days

**subchronic exposure** multiple or continuous exposures lasting for approximately 10 percent of an experimental species' lifetime, usually over a three-month period

**sublimation** the direct conversion of a solid to a gas without first changing to a liquid

**submerged aquatic vegetation** vegetation that lives at or below the water surface; an important habitat for young fish and other aquatic organisms

**substance** matter that cannot be separated into component parts by a physical process

**subwatershed** topographic perimeter of the catchment area of a stream tributary

**succession** a change in the composition and structure of an ecosystem as the available competing organisms respond to and modify the environment

**sump** a below-grade level pit or tank that catches liquid runoff for drainage or disposal

**superchlorination** chlorination with doses that are deliberately selected to produce water free of combined residuals so large as to require dechlorination

**supercritical water** a type of thermal treatment using moderate temperatures and high pressures to enhance the ability of water to break down large organic molecules into smaller, less toxic ones. Oxygen injected during this process combines with simple organic compounds to form carbon dioxide and water

**Superfund Innovative Technology Evaluation (SITE) Program** an EPA program to promote development and use of innovative treatment and site characterization technologies in Superfund site cleanups

**surface impoundment** a below-land surface pond or basin used for the treatment, storage, or disposal of liquid hazardous wastes

**surface runoff** precipitation, snowmelt, or irrigation water in excess of that which can infiltrate the soil surface and be stored in small surface depressions; a major transporter of nonpoint source pollutants in rivers, streams, and lakes

**surface water** all water naturally open to the atmosphere (rivers, lakes, reservoirs, ponds, streams, impoundments, seas, estuaries, etc.)

**Surface-Water Treatment Rule** rule that specifies maximal contaminant level goals for *Giardia lamblia*, viruses, and *Legionella* with filtration and disinfection requirements for public water systems using surface-water or groundwater sources under the direct influence of surface water. The regulations also specify water quality, treatment, and watershed protection criteria

**surfacing ACM** asbestos-containing material that is sprayed or troweled on or otherwise applied to surfaces, such as acoustical plaster on ceilings and fireproofing materials on structural members

**surfacing material** material sprayed or troweled onto structural members (beams, columns, or decking) for fire protection; or on ceilings or walls for fireproofing, acoustical, or decorative purposes. Includes textured plaster and other textured wall and ceiling surfaces

**surfactant** a detergent compound that promotes lathering (formation of suds)

**surrogate data** data from studies of test organisms or a test substance that are used to estimate the characteristics of or effects on a related organism or substance

**surveillance system** a series of monitoring devices designed to check on environmental conditions

**susceptibility analysis** an analysis to determine whether a public water supply is subject to significant pollution from known potential sources

**suspect material** building material suspected of containing asbestos (e.g., surfacing material, floor tile, ceiling tile, thermal system insulation)

**suspended loads** specific sediment particles maintained in the water column by turbulence and carried with the flow of water

**suspended solids** small particles of solid pollutants that float on the surface of, or are suspended in, sewage or other liquids. They resist removal by conventional means

**suspension culture** cells growing in a liquid nutrient medium

**sustainable development (sustainability)** the use of renewable and nonrenewable natural resources in a manner that satisfies current economic and societal needs without compromising the availability of these resources for future generations

**swamp** a type of wetland dominated by woody vegetation but without appreciable peat deposits. Swamps may be freshwater or salt water and tidal or nontidal

**symbiosis** mutualistic relationship of different species that live close together

**synergism** an interaction of two or more chemicals that results in an effect greater than the sum of their separate effects

**synthetic organic chemicals (SOCs)** anthropogenic organic chemicals. Some SOC are volatile; others tend to stay dissolved in water instead of evaporating

**system** in ecology, a network of interacting and interconnected physical, biological, and chemical relationships

**systemic pesticide** a chemical absorbed by an organism that interacts with the organism and makes it toxic to pests

**system with a single service connection** a system that supplies drinking water to consumers via a single service line

**tailings** residue of raw material or waste separated out during the processing of crops or mineral ores

**tailpipe standards** emission limitations applicable to mobile source engine exhausts

**tail water** the runoff of irrigation water from the lower end of a field

**tar sands** sand deposits containing heavy petroleum compound (bitumen) that is too thick to

be pumped. Tar sands are excavated and heated with steam to separate the bitumen and allow its processing into usable petroleum products

**Technical Assistance Grant (TAG)** as part of the Superfund program, Technical Assistance Grants of up to \$50,000 are provided to citizens' groups to obtain assistance in interpreting information related to cleanups at Superfund sites or those proposed for the National Priorities List. Grants are used by such groups to hire technical advisers to help them understand the site-related technical information for the duration of response activities

**technology-based limitations** industry-specific wastewater limits based on best available preventive technology applied to a discharge when it will not cause a violation of water quality standards at low stream flows. Usually applied to discharges into large rivers

**technology-based standards** industry-specific wastewater limits applicable to direct and indirect sources that are developed on a category-by-category basis using statutory factors, not including water-quality effects

**teratogen** a substance capable of causing birth defects

**teratogenesis** the introduction of nonhereditary birth defects in a developing fetus by exogenous factors such as physical or chemical agents acting in the womb that interfere with normal embryonic development

**terracing** the practice of building walls or dikes along the contour of sloping farmland that hold runoff and sediment to reduce erosion

**tertiary treatment** advanced cleaning of wastewater that goes beyond the secondary or biological stage, removing nutrients such as phosphorus, nitrogen, and most biological oxygen demand (BOD) and suspended solids

**theoretical maximum residue contribution (TMRC)** the theoretical maximal amount of a pesticide in the daily diet of an average person. It assumes that the diet is composed of all food items for which there are tolerance-level residues of the pesticide. The TMRC is expressed as milligrams of pesticide per kilograms of body weight per day

**therapeutic index** the ratio of the dose required to produce toxic or lethal effects to the dose required to produce nonadverse or therapeutic response

**thermal pollution** discharge of heated water from industrial processes that can kill or injure aquatic organisms

**thermal stratification** the formation of layers of different temperatures in a lake or reservoir

**thermal system insulation (TSI)** asbestos-containing material applied to pipes, fittings, boilers, breeching, tanks, ducts, or other interior structural components to prevent heat loss or gain or water condensation

**thermal treatment** use of elevated temperatures to treat hazardous wastes

**thermochemistry** the study of the relationship between heat and chemical reactions

**thermocline** the middle layer of a thermally stratified lake or reservoir. In this layer, there is a rapid decrease in temperatures in a lake or reservoir

**threshold** the dose or exposure level below which a significant adverse effect is not expected

**threshold level** time-weighted average pollutant concentration values, exposure beyond which is likely to adversely affect human health

**threshold limit value (TLV)** the concentration of an airborne substance to which an average person can be repeatedly exposed without adverse effects. TLVs may be expressed as either TLV-TWA (time-weighted average), based on an allowable exposure averaged over a normal eight-hour workday or 40-hour workweek; or TLV-STEL (short-term exposure limit), the maximum concentration for a brief specified period, depending on a specific chemical; or TLV-C (ceiling exposure limit), the maximum exposure concentration not to be exceeded under any circumstances

**Threshold Planning Quantity** a quantity designated for each chemical on the list of extremely hazardous substances that triggers notification by facilities to the State Emergency Response Commission that such facilities are subject to emergency planning requirements under SARA Title III

**tidal marsh** low, flat marshlands traversed by channels and tidal hollows, subject to tidal inundation; normally, the only vegetation present are salt-tolerant bushes and grasses

**time-weighted average (TWA)** in air sampling, the average air concentration of contaminants during a given period

**tolerances** permissible residue levels for pesticides in raw agricultural produce and processed foods. Whenever a pesticide is registered for use on a food or a feed crop, a tolerance (or exemption from the tolerance requirement) must be established. The EPA establishes the tolerance levels, which are enforced by the Food and Drug Administration and the Department of Agriculture

**tonnage** the amount of waste that a landfill accepts, usually expressed in tons per month.

The rate at which a landfill accepts waste is limited by the landfill's permit

**topsoil** that portion of the soil that is most supportive of plant growth and is very important for ecosystem sustainability and agriculture

**total dissolved phosphorus** the total phosphorus content of all material that will pass through a filter, which is determined as orthophosphate without prior digestion or hydrolysis

**total dissolved solids (TDS)** all solid material that passes through a 2-micron-size sieve or filter. Term is used to reflect hardness

**Total Maximum Daily Load (TMDL)** a calculation of the highest amount of a pollutant that a water body can receive and safely meet water quality standards set by the state, territory, or authorized tribe

**total petroleum hydrocarbons (TPH)** measure of the concentration or mass of petroleum hydrocarbon constituents present in a given amount of soil or water

**total recovered petroleum hydrocarbon** a method for measuring petroleum hydrocarbons in samples of soil or water

**total suspended particles (TSP)** a method of monitoring airborne particulate matter by total weight

**total suspended solids (TSS)** a measure of the suspended solids (of a specified size) in wastewater, effluent, or water bodies

**toxicant** a harmful substance or agent that may injure an exposed organism

**toxic chemical** any chemical listed in the EPA rules as Toxic Chemicals Subject to Section 313 of the Emergency Planning and Community Right-to-Know Act of 1986

**Toxic Chemical Release Form** information form required of facilities that manufacture, process, or use chemicals listed under SARA Title III

**toxic chemical use substitution** replacing toxic chemicals with less harmful chemicals in industrial processes

**toxic cloud** airborne plume of gases, vapors, fumes, or aerosols containing toxic materials

**toxic concentration** the concentration at which a substance produces a toxic effect

**toxic dose** the dose level at which a substance produces a toxic effect

**toxicity** the degree to which a substance or mixture of substances can harm humans or animals. ACUTE TOXICITY involves harmful effects in an organism through a single or short-term exposure. CHRONIC TOXICITY is the ability of a substance or mixture of substances to cause harmful effects over an extended period, usually

upon repeated or continuous exposure, sometimes lasting for the entire life of the exposed organism. **SUBCHRONIC TOXICITY** is the ability of the substance to cause effects for more than one year but less than the lifetime of the exposed organism

**toxicity assessment** characterization of the toxicological properties and effects of a chemical, with special emphasis on establishment of dose-response characteristics

**toxicity testing** biological testing (usually with an invertebrate, fish, or small mammal) to determine the adverse effects of a compound or wastewater

**toxicological profile** an examination, summary, and interpretation of a hazardous substance to determine levels of exposure and associated health effects

**toxic pollutants** materials that cause death, disease, or birth defects in organisms that ingest or absorb them. The quantities and exposures necessary to cause these effects can vary widely

**toxic release inventory (TRI)** database of toxic releases in the United States compiled from SARA Title III Section 313 reports

**toxic substance** a chemical or mixture that may present an unreasonable risk of injury to health or the environment

**toxic waste** a waste that can produce injury if inhaled, swallowed, or absorbed through the skin

**transboundary pollutants** air pollution that travels from one jurisdiction to another, often crossing state or international boundaries. Also applies to water pollution

**transfer station** facility where solid waste is transferred from collection vehicles to larger trucks or railcars for longer-distance transport. Limited processing of waste (compaction, bailing) also may occur at these sites.

**transient water system** a noncommunity water system that does not serve 25 of the same non-residents per day for more than six months per year

**transmission lines** pipelines that transport raw water from its source to a water treatment plant, then to the distribution grid system

**transmissivity** the ability of an aquifer to transmit water

**transpiration** the process by which water vapor is lost to the atmosphere from living plants

**transportation control measures (TCMs)** steps taken by a locality to reduce vehicular emission and improve air quality by reducing or changing the flow of traffic (e.g., bus and HOV lanes, car-

pooling and other forms of ride sharing, public transit, bicycle lanes)

**transporter** hauling firm that picks up properly packaged and labeled hazardous waste from generators and transports it to designated facilities for treatment, storage, or disposal. Transporters are subject to EPA and DOT hazardous waste regulations

**trash** material considered worthless or offensive that is thrown away. Generally defined as dry waste material, but in common usage it is a synonym for garbage, rubbish, or refuse

**trash-to-energy plan** burning trash to produce energy

**treatability studies** tests of potential cleanup technologies conducted in a laboratory

**treated regulated medical waste** medical waste that has been treated to reduce substantially or eliminate its pathogenicity but that has not yet been destroyed

**treated wastewater** wastewater that has been subjected to one or more physical, chemical, and biological processes to reduce its potential as a health hazard

**treatment** any method, technique, or process designed to remove solids and/or pollutants from solid waste, waste streams, effluents, and air emissions. Also, methods used to change the biological character or composition of any regulated medical waste to reduce substantially or eliminate its potential for causing disease

**treatment plant** a structure built to treat wastewater before discharging it into the environment

**Treatment, Storage, and Disposal Facility (TSD, TSDF)** a site where a hazardous substance is treated, stored, or disposed. TSD facilities are regulated by EPA and states under RCRA

**trial burn** an incinerator test in which emissions are monitored for the presence of specific organic compounds, particulates, and hydrogen chloride

**tributary** any surface water body that contributes water to a stream or river

**trickle irrigation** method in which water drips to the soil from perforated tubes or emitters

**trickling filter** a treatment system in which wastewater is trickled or sprinkled over a bed of stones or other material covered with bacteria that break down the organic waste and produce clean water

**trihalomethane (THM)** one of a family of organic compounds named as derivatives of methane. THMs are generally by-products of chlorination of drinking water that contains organic material

**trophic levels** a functional classification of species that is based on feeding relationships (e.g., generally aquatic and terrestrial green plants

compose the first trophic level, and herbivores compose the second

**troposphere** the layer of the atmosphere closest to the Earth's surface

**trust fund (CERCLA)** a fund set up under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) to help pay for cleanup of hazardous waste sites and for legal action to force those responsible for the sites to clean them up

**tsunami** a large sea wave produced by a submarine earthquake, landslide, or volcano

**tuberculation** development or formation of small mounds of corrosion products on the inside of iron pipe. These tubercles roughen the inside of the pipe, increasing its resistance to water flow

**tube settler** device using bundles of tubes to let solids in water settle to the bottom for removal by conventional sludge collection means; sometimes used in sedimentation basins and clarifiers to improve particle removal

**turbidimeter** a device that measures the cloudiness of suspended solids in a liquid; a measure of the quantity of suspended solids

**turbidity** haziness in air caused by the presence of particles and pollutants. In water quality measurements, a cloudy condition in water due to suspended silt or organic matter

**turnover** a process occurring in fall and spring in some lakes where deep, cold water rises to the surface and warmer, near-surface water moves to the bottom. Turnover is an important mechanism in the replenishment of dissolved oxygen and distribution of nutrients throughout the water column

**ultraclean coal (UCC)** coal that is washed, ground into fine particles, and chemically treated to remove sulfur, ash, silicone, and other substances; usually briquetted and coated with a sealant; generates very low emissions when burned

**ultraviolet rays** UV rays from one part of the spectrum (UV-A) enhance plant life. UV rays from other parts of the spectrum (UV-B) can cause skin cancer or other tissue damage. The ozone layer in the atmosphere partly shields the Earth's surface from ultraviolet rays

**uncertainty** related to precision. Measurements of high precision have low uncertainty

**uncertainty factor (UF)** one of several factors used in calculating the reference dose from experimental data. UFs are intended to account for the variation in sensitivity among humans, the uncertainty in extrapolating animal data to humans, the uncertainty in extrapolating data

obtained in a study that covers less than the full life of the exposed animal or human, and the uncertainty in using LOAEL data rather than NOAEL data

**unconfined aquifer** an aquifer containing water that is not under pressure; the water level in a well is the same as the level of the water table outside the well

**Underground Injection Control (UIC)** the program under the Safe Drinking Water Act that regulates the use of wells to pump fluids into the ground

**underground injection wells** steel- and concrete-encased shafts into which hazardous waste is deposited by force and under pressure

**underground mine** a mine consisting of subterranean passages that commonly follow ore veins or coal seams

**underground sources of drinking water** aquifers currently being used as a source of drinking water or those capable of supplying a public water system. They have a total dissolved solids content of 10,000 milligrams per liter or less

**unreasonable risk** any unjustifiable risk to people or the environment, taking into account the medical, economic, social, and environmental costs and benefits of any pesticide or chemical product

**unsaturated zone** the area above the water table where soil pores are not fully saturated, although some water may be present

**upper detection limit** the largest concentration that an instrument can reliably detect

**upslope fog** fog that forms when air cools as it flows along a land surface that is increasing in elevation

**upwelling** a rising ocean current that transports water from the depths toward the surface

**uranium mill tailings piles** former uranium ore processing sites that contain radioactive materials (wastes), including radium and unrecovered uranium

**uranium mill tailings waste piles** licensed active mills with tailings piles and evaporation ponds created by acid or alkaline leaching processes

**urban runoff** storm water from city streets and adjacent domestic or commercial properties that carries pollutants of various kinds into the sewer systems and receiving waters

**urea-formaldehyde foam insulation** a material once used to conserve energy by sealing crawl spaces, attics, and so on, and no longer used because emissions were found to be a health hazard

- use cluster** a set of competing chemicals, processes, and/or technologies that can substitute for each other in performing a particular function
- used oil** spent motor oil from passenger cars and trucks collected at specified locations for recycling (not included in the category of municipal solid waste)
- utility load** the total electricity demand for a utility district
- vadose zone** the zone between land surface and the water table within which the moisture content is less than saturation (except in the capillary fringe) and pressure is less than atmospheric. Soil pore space also typically contains air or other gases. The capillary fringe is included in the vadose zone
- valued environmental attributes/components** those aspects (components, processes, or functions) of ecosystems, human health, and environmental welfare considered to be important and potentially at risk from human activity or natural hazards. Similar to the term *valued environmental components* used in Environmental Impact Assessment
- van der Waals forces** weak, intermolecular forces operating between small molecules that holds them together; a type of chemical bonding or attraction
- vapor** the gas given off by substances that are solids or liquids at ordinary atmospheric pressure and temperatures
- vapor capture system** any combination of hoods and ventilation systems that captures or contains vapors so they may be directed to an abatement or recovery device
- vapor dispersion** the movement of vapor clouds in air due to wind, thermal action, gravity spreading, and mixing
- vapor plumes** flue gases visible because they contain water droplets
- vapor pressure** a measure of a substance's propensity to evaporate. Vapor pressure is the force per unit area exerted by vapor in an equilibrium state with surroundings at a given pressure. It increases exponentially with an increase in temperature. Also a relative measure of chemical volatility, vapor pressure is used to calculate water partition coefficients and volatilization rate constants
- vapor recovery system** a system by which the volatile gases from gasoline storage and handling are captured instead of being released into the atmosphere
- variance** government permission for a delay or exception in the application of a given law, ordinance, or regulation
- vector** an organism, often an insect or rodent, that carries disease. Also, plasmids, viruses, or bacteria used to transport genes into a host cell. A gene is placed in the vector; the vector then infects the bacterium
- vegetative controls** nonpoint source pollution control practices that involve vegetative cover to reduce erosion and minimize migration of pollutants
- ventilation rate** the rate at which indoor air enters and leaves a building. Expressed as the number of changes of outdoor air per unit of time (air changes per hour [ACH]) or the rate at which a volume of outdoor air enters at a given rate (e.g., cubic feet per minute [CFM])
- ventilation/suction** the act of admitting fresh air into a space in order to replace stale or contaminated air; achieved by blowing air into the space. Similarly, suction represents the admission of fresh air into an interior space by lowering the pressure outside the space, thereby drawing the contaminated air outward
- venturi scrubbers** air pollution control devices that use water to remove particulate matter from emissions
- virgin materials** resources extracted from nature in their raw form, such as timber or metal ore
- viscosity** the molecular friction within a fluid that produces flow resistance
- volatile** any substance that evaporates readily
- volatile liquids** liquids that readily vaporize or evaporate at room temperature
- volatile solids** those solids in water or other liquids that are lost on ignition of the dry solids at 550°C
- volatile synthetic organic chemicals (VSOCs)** synthesized chemicals that tend to volatilize or evaporate
- volume reduction** processing waste materials to decrease the amount of space they occupy, usually by compacting, shredding, incineration, or composting
- volumetric tank test** one of several tests to determine the physical integrity of a storage tank. The volume of fluid in the tank is measured directly or calculated from product-level changes. A marked drop in volume over a specified period indicates a leak
- vulnerability analysis** assessment of elements in the community that are susceptible to damage if hazardous materials are released

**vulnerable zone** an area over which the concentration of a chemical accidentally released could reach the level of concern

**waste** unwanted materials left over from a manufacturing process. Also, refuse from places of human or animal habitation

**waste characterization** identification of chemical and microbiological constituents of a waste material

**waste exchange** arrangement in which companies exchange their wastes for the benefit of both parties

**waste feed** the continuous or intermittent flow of wastes into an incinerator

**waste generation** the weight or volume of materials and products that enter the waste stream before recycling, composting, landfilling, or combustion takes place. Also can represent the amount of waste generated by a given source or category of sources

**waste-heat recovery** recovering heat discharged as a by-product of one process to provide heat needed by a second process

**waste load allocation** the maximum amount of pollutants each discharger of waste is allowed to release into a particular waterway. Discharge limits are usually required for each specific water quality criterion that is or expected to be violated. Also, the portion of a stream's total assimilative capacity assigned to an individual discharge

**waste minimization** measures or techniques that reduce the amount of wastes generated during industrial production processes; term is also applied to recycling and other efforts to reduce the amount of waste entering the waste stream

**waste piles** noncontainerized, lined, or unlined accumulations of solid, nonflowing waste

**waste reduction** using source reduction, recycling, or composting to prevent or reduce waste generation

**waste stream** the total flow of solid waste from homes, businesses, institutions, and manufacturing plants that is recycled, burned, or disposed of in landfills

**waste-to-energy facility/municipal-waste combustor** facility where recovered municipal solid waste is converted into a usable form of energy, usually via combustion

**waste treatment lagoon** impoundment made by excavation of soil for biological treatment of wastewater

**waste treatment plant** a facility containing a series of tanks, screens, filters, and other processes by which pollutants are removed from water

**wastewater** the spent or used water from a home, community, farm, or industry that contains dissolved or suspended matter

**wastewater infrastructure** the plan or network for the collection, treatment, and disposal of sewage in a community. The level of treatment depends on the size of the community, the type of discharge, and/or the designated use of the receiving water

**wastewater operations and maintenance** actions taken after construction to ensure that facilities developed to treat wastewater will be operated, maintained, and managed to achieve prescribed levels in an optimal manner

**wastewater treatment plan** a facility containing a series of tanks, screens, filters, and other processes by which pollutants are removed from water. Most treatments include chlorination to attain safe drinking water standards

**waterborne disease outbreak** the significant occurrence of acute illness associated with drinking water from a public water system that is deficient in treatment, as determined by appropriate local or state agencies

**water purveyor** a public utility, mutual water company, county water district, or municipality that delivers drinking water to customers

**water quality-based limitations** limitations applied to dischargers when technology-based limitations would cause violations of water quality standards. Usually applied to discharges into small streams

**water quality-based permit** a permit with an effluent limit more stringent than one based on technology performance. Such limits may be necessary to protect the designated use of receiving waters (e.g., recreation, irrigation, industry, or water supply)

**water quality criteria** levels of water quality expected to render a body of water suitable for its designated use. Criteria are based on specific levels of pollutants that make the water harmful if used for drinking, swimming, irrigation, fish production, or industrial processes

**water quality standards** state-adopted and EPA-approved ambient standards for water bodies. The standards prescribe the use of the water body and establish the water quality criteria that must be met to protect designated uses

**watershed** the land area that drains into a stream. The watershed for a major river may encompass a number of smaller watersheds that ultimately combine at a common point

**watershed approach** a coordinated framework for environmental management that focuses public and private efforts on the highest-priority

problems within hydrologically defined geographic areas, taking into consideration both groundwater and surface water flow

**water solubility** the maximum possible concentration of a chemical compound dissolved in water. If a substance is water-soluble, it can very readily disperse through the environment

**water-soluble packaging** packaging that dissolves in water; used to reduce exposure risks to pesticide mixers and loaders

**water-source heat pump** heat pump that uses wells or heat exchangers to transfer heat from water to the inside of a building. Most such units use groundwater

**water storage pond** an impoundment for liquid wastes designed to accomplish some degree of biochemical treatment

**water supplier** one who owns or operates a public water system

**water supply system** the collection, treatment, storage, and distribution of potable water from source to consumer

**water table** the level of groundwater in an aquifer or other water-bearing zone. The upper surface of groundwater at the top of the zone of saturation and below the zone of aeration

**water treatment lagoon** an impoundment for liquid wastes designed to accomplish some degree of biochemical treatment

**water well** an excavation where the intended use is for location, acquisition, development, or artificial recharge of groundwater.

**wave** a periodic disturbance in a medium that is described by specifying its amplitude, speed, wavelength, and frequency

**wave height** the vertical distance from the crest to the trough of a wave

**wavelength** the distance from one crest or trough of a wave to the next

**weight of scientific evidence** considerations in assessing the interpretation of published information about toxicity—quality of testing methods, size, and power of study design, consistency of results across studies, and biological plausibility of exposure-response relationships and statistical associations

**weir** a wall or plate placed in an open channel to measure the flow of water. Also, a wall or obstruction used to control flow from settling tanks and clarifiers to ensure a uniform flow rate and prevent short-circuiting

**well field** area containing one or more wells that produce usable amounts of water or oil

**wellhead protection area** a protected surface and subsurface zone surrounding a well or well field supplying a public water system. Land use

in these areas is restricted or tightly regulated in order to prevent contaminants from reaching the well water

**well injection** the subsurface forcing of fluids into a well

**well monitoring** measurement of well water quality by on-site instruments or laboratory methods

**well plug** a watertight, gastight seal installed in a borehole or well to prevent movement of fluids

**well point** a hollow vertical tube, rod, or pipe terminating in a perforated pointed shoe or bit and fitted with a fine-mesh screen

**wettability** the relative degree to which a fluid will spread into or coat a solid surface in the presence of other immiscible fluids

**wettable powder** dry formulation that must be mixed with water or other liquid before it is applied

**wheeling** the transmission of electricity owned by one entity through the facilities owned by another (usually a utility)

**whole-effluent-toxicity tests** tests to determine the toxicity levels of the total effluent from a single source, as opposed to a series of tests for individual contaminants

**wildlife refuge** an area designated for the protection of wild animals, within which hunting and fishing are either prohibited or strictly controlled

**wind turbine** a mechanical device that converts the wind's kinetic energy (energy of motion) into electrical energy

**wood-burning-stove pollution** air pollution caused by emissions of particulate matter, carbon monoxide, total suspended particulates, and polycyclic organic matter from wood-burning stoves

**wood treatment facility** an industrial facility that treats lumber and other wood products for outdoor use. The process employs chromated copper arsenate, which is regulated as a hazardous material

**working level (WL)** a unit of measure for documenting exposure to radon decay products. One working level is equal to approximately 200 picocuries per liter

**working level month (WLM)** a unit of measure used to determine cumulative exposure to radon

**yellow-boy** iron oxide flocculent (clumps of solids in waste or water); usually observed as orange-yellow deposits in surface streams with excess iron content. Commonly associated with acid mine drainage

**yield** the quantity of water (expressed as a rate of flow or total quantity per year) that can be collected for a given use from surface water or groundwater sources

**zero air** atmospheric air purified to contain less than 0.1 part per million (ppm) total hydrocarbons

**zero emission vehicles** private and public transportation devices, typically powered by electricity, that have no direct emissions

**zone of aeration** a subsurface zone above the water table that may be moist but not saturated. It lies above the zone of saturation

**zone of saturation** the layer beneath the surface of the land containing openings that may fill with water

**zoning** the organization or partitioning of land areas for various types of usage in cities, boroughs, or townships

**zooplankton** small (often microscopic) free-floating aquatic plants or animals

A classic and widely adopted college textbook on environmental issues and their importance in politics on a global scale but primarily in the United States.
- Vigil, Kenneth M. *Clean Water: An Introduction to Water Quality and Pollution Control* 2nd ed. Eugene: Oregon State University Press, 2003. A comprehensive introduction to the scientific, geographic, and regulatory issues that concern water quality and the control of water pollution.
- Wadden, R. A., and P. A. Scheff. *Indoor Air Pollution—Characterization, Prediction and Control*. New York: John Wiley & Sons, 1983. A basic but comprehensive text on all aspects of indoor air pollutants, their sources, controls, and fate.
- Ward, Andy D., and Stanley W. Trimble. *Environmental Hydrology*, 2nd ed. Boca Raton, Fla.: CRC Press, 2004. A comprehensive hydrogeology overview that includes information on hydrologic processes based upon results of new information technology tools such as remote sensing and geographic information systems that are invaluable for the study of wetlands, agricultural land, and land use change.
- Wiedemeier, Todd H., Hanadi S. Rifai, John T. Wilson, and Charles Newell. *Natural Attenuation of Fuels and Chlorinated Solvents in the Subsurface*. New York: John Wiley & Sons, 1999. A technical reference for environmental remediation in which the natural breakdown of fuels and chlorinated solvents is a significant part of the study.
- World Health Organization. *Air Quality Guidelines*, 2nd ed. Copenhagen: WHO Regional Office for Europe, 2000. A technical set of guidelines and recommendations for air quality based upon scientific environmental and epidemiological findings.
- . *Guidelines for Drinking Water Quality*, 2nd ed., Geneva: World Health Organization, 2006. A technical set of guidelines and recommendations for drinking water quality based upon scientific environmental and epidemiological findings.
- . *World Health Organization Environmental Health Criteria Report*. Geneva: World Health Organization, 1985. Report of a committee of experts establishing health criteria to govern human limits of exposure to environmental pollutants.
- Younger, Paul L., Steven A. Banwart, and Robert S. Hedin. *Mine Water: Hydrology, Pollution, Remediation*. Dordrecht, Netherlands: Kluwer Academic, 2002. A basic but comprehensive text on the generation, dispersion, and remediation of contaminated surface and groundwater from mines.

## INTERNET RESOURCES

Agency for Toxic Substances and Disease Registry [ATSDR].

“Toxicological Profiles.” Available online. URL: <http://www.atsdr.cdc.gov/toxprofiles/>. Accessed February 18, 2011. A very comprehensive Web site maintained by the U.S. Department of Health and Human Services that contains epidemiological data on exposure to all chemicals that can have adverse effects on humans including those considered to be environmental pollutants.

———. “2007 CERCLA Priority List of Hazardous Substances.” Available online. URL: <http://www.atsdr.cdc.gov/cercla/07list.html>. Accessed February 18, 2011. The biannual rankings of the 275 most toxic environmental pollutants as determined by the federal government. Previous rankings are also available at this site.

Blacksmith Institute. “World’s Worst Pollution Problems.” Available online. URL: <http://www.worstpolluted.org/>. Accessed February 18, 2011. A full description of the 10 worst polluted sites in the world as determined by the Blacksmith Institute for the current year. Descriptions of sites from previous years are also available.

Center of Documentation, Research and Experimentation on Accidental Water Pollution (Cedre). Available online. URL: <http://www.cedre.fr/uk/spill/>. Accessed February 18, 2011. Full accounts of recent major oil spills in the ocean and an archive of previous major marine oil spills.

Commodity Statistics and Information: U.S. Geological Survey. Available online. URL: <http://minerals.usgs.gov/minerals/pubs/commodity/index.html>. Accessed February 18, 2011. Full current statistics for production and consumption of mineral commodities in the United States and an archive of previous years. Professional articles on mining, use, and disposal are available for some commodities.

EXTOXNET. “Pesticide Information Profiles.” Extension Toxicology Network, Oregon State University, 1996. Available online. URL: <http://extoxnet.orst.edu/pips/ghindex.html>. Accessed February 18, 2011. Descriptions of application, consumption, toxicology, persistence, and general environmental effects of numerous individual pesticides that are widely used in the United States.

Federal Remediation Technologies Roundtable [FRTR]. Available online. URL: <http://www.frtr.gov/default.htm>. Accessed February 18, 2011. Full descriptions, diagrams, and technical applications of federally accepted remedial methods for polluted groundwater, surface water and soils/sediments. Reports of new pollution issues addressed by the EPA, NASA, DOE, and Department of Defense are also available.

Greenpeace International. Available online. URL: <http://www.greenpeace.org/international/>. Accessed February 18, 2011. Current environmental activist efforts are described, as well as the history of activities in archives.

National Institute of Occupational Safety and Health [NIOSH]. “National Occupational Exposure Survey (NOES) of 1981–1983.” Available online. URL: <http://www.cdc.gov/noes/noes1/agtindex.html>. Accessed February 18, 2011. Web site presenting the total annual exposure of American workers to all regulated industrial chemicals and substances during the years 1981–1983.

Natural Resources Defense Council. Available online. URL: <http://www.nrdc.org/>. Accessed February 18, 2011. Web site containing information on a variety of environmental pollutants as well as articles on pollutants and environmental policy.

Pesticide Management Education Program [PMEP]. “Pesticide Active Ingredient Information.” Cornell University Extension Service. Available online. URL: <http://pmep.cce.cornell.edu/profiles/>. Accessed February 18, 2011. Full epidemiological reports on numerous pesticides including use, distribution, persistence, and effect on plants and other organisms.

Report on Carcinogens, 11th ed.: National Toxicology Program, U.S. Department of Health and Human Services, Public Health Service, 2005. Available online. URL: <http://ntp.niehs.nih.gov/ntp/roc/toc11.html>. Accessed February 18, 2011. A regularly released report on all aspects of known carcinogens that is available on the Internet. Data include uses, production, epidemiology, classifications, chemistry, and results of toxicological studies.

Risk Assessment Information System: Toxicity Profiles. Available online. URL: <http://rais.ornl.gov/>. Accessed February 18, 2011. Web site containing a complete summary of epidemiological information for many of the industrial toxicants including those commonly released to the environment.

United Nations, Office for the Coordination of Humanitarian Affairs [OCHA]. “Environmental Disaster Reports.” Available online. URL: <http://www.reliefweb.int/ochaunep/edr/index.htm>. Accessed February 18, 2011. Web site containing descriptions of severely polluted sites on a worldwide basis where the United Nations has played a role.

U.S. Environmental Protection Agency [EPA]. Available online. URL: <http://www.epa.gov/>. Accessed February 18, 2011. Web site with links to all pollution information in the United States including pollutants, regulation, legislation, polluted sites, and epidemiology.

———. “Clean-up Information: Technology, Remediation.” Updated December 29, 2010. Available online. URL: <http://www.clu-in.org/remediation/>. Accessed February 17, 2011. Description of EPA recommended remediation methods and devices for groundwater pollution.

———. “Drinking Water Contaminants.” Available online. URL: <http://water.epa.gov/drink/contaminants/index.cfm>. Accessed February 17, 2011. Complete descriptions of production, use, toxicology, epidemiology, and environmental effects for various pesticides, organic

pollutants, inorganic pollutants, radioactive elements, and microbes of particular concern.

———. “Integrated Risk Information System (IRIS): A–Z List of Substances.” Updated February 17, 2011. Available online. URL: <http://cfpub.epa.gov/ncea/iris/index.cfm?fuseaction=iris.showSubstanceList>. Accessed February 17, 2011. Web site containing the results of all of the scientific studies of the effects of exposure to organic and inorganic chemical pollutants and their presence in the environment.

———. “Superfund: Cleaning up the Nation’s Hazardous Wastes Sites.” Updated February 14, 2011. Available online. URL: <http://www.epa.gov/superfund/index.htm>. Accessed February 18, 2011. Web site contains links to all information on Superfund sites, including locations, site descriptions, history, archives, legislative actions, and press releases.

———. “Technology Transfer Network Air Toxics Web Site: Health Effects Notebook for Hazardous Air Pol-

lutants.” Updated April 5, 2010. Available online. URL: <http://www.epa.gov/ttn/atw/hlthef/hapindex.html>. Accessed February 18, 2011. Technical information on specific air pollutants, including source, location, regulations, epidemiology, and fate.

———. “TRI Explorer: Chemical Report.” Available online. URL:

<http://www.epa.gov/triexplorer/>. Accessed February 18, 2011. Web site containing all reported releases of all industrial pollutants to the environment, including on-site and off-site disposal, with an archive for every year that data have been collected.

U.S. Food and Drug Administration. “Bad Bug Book: Food-borne Pathogenic Microorganisms and Natural Toxins Handbook, 1998.” Available online. URL: <http://www.cfsan.fda.gov/~mow/intro.html>. Accessed February 18, 2011. Information on all living pollutants both indoor and outdoor including sources, distribution, life cycle, epidemiology, case histories, and preventative measures.

# APPENDIX V

## 2007 CERCLA PRIORITY LIST OF HAZARDOUS SUBSTANCES

Note: The following CERCLA Priority List of Hazardous Substances is prepared by the U.S. Environmental Protection Agency using relevant toxicology and abundance documentation, and it is distributed by the Agency for Toxic Substances and Disease Registry (ATSDR) of the U.S. Department of Health and Human Services. The rankings are accurate as of January 2011.

2007 Rank	Substance Name	2005 Rank
1	Arsenic	1
2	Lead	2
3	Mercury	3
4	Vinyl Chloride	4
5	Polychlorinated Biphenyls (PCB)	5
6	Benzene	6
7	Cadmium	8
8	Polycyclic Aromatic Hydrocarbons (PAH)	7
9	Benzo(A)Pyrene (PAH)	9
10	Benzo(B)Fluoranthene (PAH)	10
11	Chloroform	11
12	DDT, P,P'-	12
13	Aroclor 1254 (PCB)	13
14	Aroclor 1260 (PCB)	14
15	Dibenzo(A,H)Anthracene (PAH)	15
16	Trichloroethylene (TCE)	16
17	Dieldrin	17
19	Phosphorus, White	19
18	Chromium, Hexavalent	18
20	Chlordane	21
21	DDE, P,P'-	20
22	Hexachlorobutadiene (HCB)	22

2007 Rank	Substance Name	2005 Rank
23	Coal Tar Creosote	23
24	Aldrin	25
25	DDD, P,P'-	24
26	Benzidine	26
27	Aroclor 1248 (PCB)	27
28	Cyanide	28
29	Aroclor 1242 (PCB)	29
30	Aroclor (PCB)	62
31	Toxaphene	30
32	Hexachlorocyclohexane, Gamma- (HCH)	32
33	Tetrachloroethylene (PCE)	31
34	Heptachlor	33
35	1,2-Dibromoethane	34
36	Hexachlorocyclohexane, Beta- (HCH)	37
37	Acrolein	36
38	Disulfoton	35
39	Benzo(A)Anthracene (PAH)	38
40	3,3'-Dichlorobenzidine (DCB)	39
41	Endrin	41
42	Beryllium	40
43	Hexachlorocyclohexane, Delta- (HCH)	42
44	1,2-Dibromo-3-Chloropropane (DBCP)	43
45	Pentachlorophenol (PCP)	45
46	Heptachlor Epoxide	44
47	Carbon Tetrachloride	46
48	Aroclor 1221 (PCB)	47
49	Cobalt	50
50	DDT, O,P'-	49
51	Aroclor 1016 (PCB)	48
52	Di-N-Butyl Phthalate (Phthalate)	52
53	Nickel	55
54	Endosulfan	54
55	Endosulfan Sulfate	53
56	Diazinon	57
57	Endosulfan, Alpha	58
58	Xylenes, Total	59
59	Cis-Chlordane	51

2007 Rank	Substance Name	2005 Rank
60	Dibromochloropropane (DBCP)	60
61	Methoxychlor	61
62	Benzo(K)Fluoranthene (PAH)	63
63	Endrin Ketone	64
64	Trans-Chlordane	56
65	Chromium(VI) Oxide	66
66	Methane	67
67	Endosulfan, Beta	65
68	Aroclor 1232 (PCB)	68
69	Endrin Aldehyde	69
70	Benzofluoranthene (PAH)	70
71	Toluene	71
72	2-Hexanone (MBK)	72
73	2,3,7,8-Tetrachlorodibenzo-P-Dioxin (Dioxin)	73
74	Zinc	74
75	Dimethylarsinic Acid	75
76	Di(2-Ethylhexyl)Phthalate (Phthalate)	76
77	Chromium	77
78	Naphthalene	78
79	1,1-Dichloroethene (DCE)	79
80	Methylene Chloride	81
81	Aroclor 1240	80
82	2,4,6-Trinitrotoluene (TNT)	82
83	Bromodichloroethane (BDA)	83
84	Hydrazine	85
85	1,2-Dichloroethane (DCA)	84
86	2,4,6-Trichlorophenol (TCP)	86
87	2,4-Dinitrophenol	87
88	Bis(2-Chloroethyl) Ether	88
89	Thiocyanate	89
90	Asbestos	90
91	Chlorine	92
92	Cyclotrimethylenetrinitramine (RDX)	91
93	Hexachlorobenzene (HCB)	93
94	2,4-Dinitrotoluene (DNT)	96
95	Radium 226	94
96	Ethion	97

2007 Rank	Substance Name	2005 Rank
97	1,1,1-Trichloroethane (TCA)	95
98	Uranium	98
99	Ethylbenzene	99
100	Radium	100
101	Thorium	101
102	4,6-Dinitro-O-Cresol	102
103	1,3,5-Trinitrobenzene	103
104	Chlorobenzene	105
105	Radon	104
106	Radium 228	106
107	Thorium 230	107
107	Uranium 235	107
109	Barium	109
110	Fluoranthene (PAH)	113
111	Uranium 234	110
112	N-Nitrosodi-N-Propylamine	111
113	Thorium 228	112
114	Radon 222	114
115	Hexachlorocyclohexane, Alpha- (HCH)	116
116	1,2,3-Trichlorobenzene (TCB)	143
117	Manganese	115
118	Coal Tars	117
119	Chrysotile Asbestos	119
119	Strontium 90	119
121	Plutonium 239	118
122	Polonium 210	122
123	Methylmercury	121
124	Plutonium 238	123
125	Lead 210	124
126	Plutonium	125
127	Chlorpyrifos	125
128	Copper	133
129	Americium 241	128
130	Radon 220	127
131	Amosite Asbestos	129
132	Iodine 131	130

2007 Rank	Substance Name	2005 Rank
133	Hydrogen Cyanide	132
134	Tributyltin	131
135	Guthion	134
136	Neptunium 237	135
137	Chrysene	139
138	Chlordecone	136
138	Iodine 129	136
138	Plutonium 240	136
141	S,S,S-Tributyl Phosphorotrithioate	140
142	Bromine	142
143	Polybrominated Biphenyls (PBB)	141
144	Dicofol	144
145	Parathion	145
146	1,1,2,2-Tetrachloroethane (PCA)	146
147	Selenium	147
148	Hexachlorocyclohexane, Technical Grade (HCH)	148
149	Trichlorofluoroethane	149
150	Trifluralin	150
151	DDD, O,P'-	151
152	4,4'-Methylenebis(2-Chloroaniline)	152
153	Hexachlorodibenzo-P-Dioxin (Dioxin)	153
154	Heptachlorodibenzo-P-Dioxin (Dioxin)	154
155	Pentachlorobenzene	155
156	1,3-Butadiene	201
157	Ammonia	156
158	2-Methylnaphthalene	157
159	1,4-Dichlorobenzene (DCB)	159
160	1,1-Dichloroethane (DCA)	158
161	Acenaphthene	160
162	1,2,3,4,6,7,8,9-Octachlorodibenzofuran (Furan)	161
163	1,1,2-Trichloroethane (TCA)	162
164	Trichloroethane (TCA)	163
165	Hexachlorocyclopentadiene (HC)	164
166	Heptachlorodibenzofuran (Furan)	165
167	1,2-Diphenylhydrazine	166
168	2,3,4,7,8-Pentachlorodibenzofuran (Furan)	167

2007 Rank	Substance Name	2005 Rank
169	Tetrachlorobiphenyl	168
170	Cresol, Para-	169
171	Oxychlordane	170
172	1,2-Dichlorobenzene (DCB)	171
173	1,2-Dichloroethene, Trans-	178
174	Indeno(1,2,3-Cd)Pyrene (PAH)	180
175	Gamma-Chlordene	172
176	Carbon Disulfide	174
177	Tetrachlorophenol	173
178	Americium	175
178	Uranium 233	175
180	Palladium	177
181	Hexachlorodibenzofuran (Furan)	179
182	Phenol	183
183	Chloroethane	182
184	Acetone	181
185	P-Xylene	185
186	Dibenzofuran (Furan)	187
187	Aluminum	186
188	2,4-Dimethylphenol	189
189	Carbon Monoxide	188
190	Tetrachloroethane (PCA)	190
191	Hydrogen Sulfide	193
192	Pentachlorodibenzofuran (Furan)	192
193	Chloromethane	191
194	Bis(2-Methoxyethyl) Phthalate (Phthalate)	194
195	Butyl Benzyl Phthalate (Phthalate)	195
196	Cresol, Ortho-	196
197	Hexachloroethane	199
198	Vanadium	198
199	N-Nitrosodimethylamine	200
200	1,2,4-Trichlorobenzene (TCB)	203
201	Bromoform	202
202	Tetrachlorodibenzo-P-Dioxin (Dioxin)	204
203	1,3-Dichlorobenzene (DCB)	205
204	Pentachlorodibenzo-P-Dioxin (Dioxin)	207

2007 Rank	Substance Name	2005 Rank
205	N-Nitrosodiphenylamine	208
206	1,2-Dichloroethylene (DCE)	206
207	2,3,7,8-Tetrachlorodibenzofuran (Furan)	210
208	2-Butanone (MEK)	209
209	2,4-Dichlorophenol	212
210	1,4-Dioxane	215
211	Fluorine	214
212	Nitrite	216
213	Cesium 137	217
214	Silver	213
215	Chromium Trioxide	218
216	Nitrate	219
217	Potassium 40	220
218	Dinitrotoluene (DNT)	221
219	Antimony	222
220	Coal Tar Pitch	224
221	Thorium 227	223
222	2,4,5-Trichlorophenol	225
223	Arsenic Acid	226
224	Arsenic Trioxide	227
225	Phorate	228
226	Benzopyrene (PAH)	230

# APPENDIX VI

## EPA TOXICS RELEASE INVENTORY (TRI) FOR INDUSTRIAL POLLUTANTS RELEASED TO THE ENVIRONMENT BY ALL INDUSTRIES IN THE UNITED STATES

Monitored Industrial Chemicals	2009 Total Reported Releases of Industrial Chemicals (in pounds [kg])	2007 Total Reported Releases of Industrial Chemical (in pounds [kg])
1,1,1,2-Tetrachloroethane	3,689 (1,677)	2,249 (1,022)
1,1,1-Trichloroethane	108,310 (49,232)	81,479 (37,036)
1,1,2,2-Tetrachloroethane	4,505 (2,048)	1,861(846)
1,1,2-Trichloroethane	16,980 (7,718)	22,367 (10,167)
1,2-Dichloroethylene	6,097 (2,771)	4,399 (2,000)
1,2-Dichloropropane	104,501 (47,500)	115,710 (52,595)
1,3-Butadiene	1,175,585 (534,357)	1,788,084 (812,765)
1,3-Dichlorobenzene	152 (69)	1,827 (830)
1,4-Dichlorobenzene	27,753 (12,615)	79,266 (36,030)
1,4-Dioxane	250,767 (113,985)	185,132 (84,151)
2,4-Dichlorophenol	27,246 (12,385)	13,541(6,155)
2,4-Dinitrotoluene	132,060 (60,027)	13,594 (6,179)
2,6-Dinitrotoluene	2,559 (1,163)	1,343 (610)
4,6-Dinitro-O-Cresol	2 (1)	104 (47)
Acrolein	566,732 (257,605)	1,696,876 (771,307)
Alachlor	7,583 (3,447)	373 (140)
Aldrin	2,149 (977)	1,128 (513)
Aniline	1,080,390 (491,350)	920,606 (418,457)
Anthracene	46,663 (21,210)	171,896 (78,135)
Antimony	979,545 (445,248)	1,312,688 (596,676)
Antimony Compounds	12,042,242 (5,473,746)	11,013,365 (5,006,075)
Arsenic	747,985 (339,766)	3,201,986 (1,455,448)
Arsenic Compounds	95,353,933 (43,342,697)	94,379,174 (42,899,625)
Asbestos (Friable)	8,757,577 (3,980,717)	10,430,381 (4,741,082)

Monitored Industrial Chemicals	2009 Total Reported Releases of Industrial Chemicals (in pounds [kg])	2007 Total Reported Releases of Industrial Chemical (in pounds [kg])
Atrazine	872,465 (396,575)	515,072 (234,124)
Barium	5,101,144 (2,318,702)	8,243,367 (3,746,985)
Barium Compounds	237,066,763 (107,757,620)	236,593,707 (107,542,593)
Benzene	4,062,618 (1,846,645)	8,465,367 (3,847,894)

Lindane	236 (107)	1,555 (707)
M-Cresol	156,150 (70,977)	192,773 (87,624)
Mercury	123,481 (56,281)	101,984 (46,356)
Mercury Compounds	6,011,831 (2,732,650)	6,833,638 (3,106,199)
Methoxychlor	2,440 (1,109)	1,050 (477)
Methyl Tert-Butyl Ether	325,209 (147,822)	585,465 (266,120)
Naphthalene	1,357,697 (617,135)	2,850,878 (1,295,854)
Nickel	5,131,571 (2,332,532)	8,212,983 (3,733,174)
Nickel Compounds	23,740,670 (10,791,214)	29,689,094 (13,495,042)
Nitrate Compounds	241,545,741 (109,793,519)	270,689,909 (123,040,864)
O-Cresol	36,105 (16,411)	20,118 (9,145)
O-Xylene	176,062 (80,028)	325,496 (147,953)
Ozone	605 (275)	704,712 (320,324)
P-Cresol	77,741 (35,337)	104,857 (47,662)
P-Xylene	944,211 (429,187)	1,311,540 (596,155)
Pentachlorobenzene	905 (411)	1,464 (665)
Pentachlorophenol	146,572 (66,624)	2,740 (1,245)
Phenol	6,323,008 (2,874,095)	6,677,767 (3,035,349)
Phosgene	13,317 (6,053)	15,290 (6,950)
Phosphorus (Yellow or White)	135,308 (61,504)	276,993 (125,906)
Polychlorinated Biphenyls	3,236,241 (1,471,019)	2,090,371 (950,169)
Polycyclic Aromatic Compounds	907,596 (412,544)	1,365,384 (620,629)
Selenium	142,762 (64,892)	1,443,711 (656,232)
Selenium Compounds	2,731,929 (1,241,786)	2,843,232 (1,292,378)
Sodium Nitrite	2,581,274 (1,173,309)	4,320,241 (1,963,746)
Styrene	19,972,424 (9,078,375)	40,748,666 (18,522,120)

Monitored Industrial Chemicals	2009 Total Reported Releases of Industrial Chemicals (in pounds [kg])	2007 Total Reported Releases of Industrial Chemical (in pounds [kg])
Styrene Oxide	32 (15)	466 (212)
Tetrachloroethylene	1,534,082 (697,310)	2,237,864 (1,017,211)
Toluene	29,051,423 (13,177,505)	41,716,513 (18,962,051)
Toluene-2,4-Diisocyanate	4,923 (2,238)	18,955 (8,616)
Toluene-2,6-Diisocyanate	1,357 (617)	3,795 (1,725)
Toxaphene	2,495 (1,134)	1,212 (551)
Trichloroethylene	2,882,252 (1,310,115)	4,485,202 (2,038,728)
Vinyl Chloride	390,531 (177,514)	372,635 (169,380)
Vinylidene Chloride	42,110 (19,141)	57,013 (25,915)
Xylene (Mixed Isomers)	14,531,035 (6,605,016)	25,595,670 (1,163,440)
Zinc (Fume or Dust)	11,910,295 (5,413,770)	69,014,216 (31,370,098)
Zinc Compounds	781,13,597 (355,056,181)	731,304,206 (332,411,003)

# APPENDIX VII

## EPA DRINKING WATER STANDARDS

### INORGANIC CHEMICALS

Category	Maximum Amount (parts per million)	Body Part Affected/Disease	Sources
Antimony (Sb)	0.006	Blood	Oil refineries, ceramics, solder
Arsenic (As)	0.005	Skin, nervous system, cancer risk	Pesticide residue, industrial and smelter waste, rocks
Asbestos	0.7	Intestines	Cement decay, deposits
Barium (Ba)	1	Heart, gastrointestinal tract, nerves, muscles	Coal power plants, jet fuels, rocks, bricks, tiles
Beryllium (Be)	0.004	Intestines	Refineries, electronics, defense industry
Cadmium (Cd)	0.01	Kidneys, blood, liver	Mining, smelting, fuel, fertilizer, rocks
Chromium (Cr)	0.05	Liver, kidneys	Mines, rocks, electronics
Copper (Cu)	1.3	Liver, kidneys, gastrointestinal tract	Plumbing, natural deposits
Cyanide	0.2	Nerves, thyroids	Discharge from steel/metal factories and plastic and fertilizer factories
Fluoride	4	Bones	Additive to water, tooth-paste, foods
Mercury (Hg)	0.002	Nervous system, kidneys	Paint, paper, vinyl, fungicide, rocks
Nitrate (Nitrogen [N])	10	Blood, cancer risk	Fertilizer, sewage, rocks
Nitrite (Nitrogen [N])	1	Blood, cancer risk	Fertilizer, sewage, rocks
Selenium (Se)	0.01	Gastrointestinal tract	Coal, refineries, glass, plants, fuel oil, rocks
Silver (Ag)	0.05	Skin	Mining, rocks
Thallium (Tl)	0.0005	Hair loss, blood, kidneys, intestines, liver	Electronics, glass, drug factories, leachate

(continues)

## ORGANIC CHEMICALS

Category	Maximum Amount (parts per million)	Body Part Affected/Disease	Sources
Alachlor	0.002	Eye, liver, kidney, or spleen; anemia, cancer risks	Runoff from herbicide used on row crops
Atrazine	0.003	Cardiovascular system or reproductive problems	Runoff from herbicide used on row crops
Benzene	0.005	Anemia, decrease in blood platelets, increased risk of cancer	Discharge from factories; leaching from gas storage tanks and landfills
Benzo(a)pyrene (PAH)s	0.0002	Reproductive difficulties, increased risk of cancer	Leaching from linings of water storage tanks and distribution lines
Carbofuran	0.04	Problems with blood, nervous system, or reproductive system	Leaching of soil fumigant used on rice and alfalfa
Carbon tetrachloride	0.005	Liver problems, increased risk of cancer	Discharge from chemical plants and other industrial activities
Chlordane	0.002	Liver, nervous system problems, increased risk of cancer	Residue of banned termiticide
Chlorobenzene	0.1	Liver, kidneys	Discharge from chemical and agricultural chemical factories
2,4-D	0.07	Kidney, liver, or adrenal gland problems	Runoff from herbicide used on row crops
Dalapon	0.2	Kidney	Runoff from herbicide
1,2-Dibromo-3-chloropropane (DBCP)	0.0002	Reproductive difficulties, increased risk of cancer	Runoff/leaching from soil fumigant used on soybeans, cotton, pineapples, and orchards
o-Dichlorobenzene	0.6	Liver, kidney, circulatory system problems	Discharge from industrial chemical factories
p-Dichlorobenzene	0.075	Anemia, liver, kidney, spleen, blood	Discharge from industrial chemical factories
1,2-Dichloroethane	0.005	Increased risk of cancer	Discharge from industrial chemical factories
1,1-Dichloroethylene	0.007	Liver	Discharge from industrial chemical factories
cis-1,2-Dichloroethylene	0.07	Liver	Discharge from industrial chemical factories
trans-1,2-Dichloroethylene	0.1	Liver	Discharge from industrial chemical factories
Dichloromethane	0.005	Liver problems, increased risk of cancer	Discharge from drug and chemical factories

**ORGANIC CHEMICALS** *(continued)*

Category	Maximum Amount (parts per million)	Body Part Affected/Disease	Sources
1,2-Dichloropropane	0.005	Cancer	Discharge from industrial chemical factories
Di(2-ethylhexyl) adipate	0.4	Weight loss, liver problems, or possible reproductive difficulties	Discharge from chemical factories
Di(2-ethylhexyl) phthalate	0.006	Reproductive difficulties, liver problems, increased risk of cancer	Discharge from rubber and chemical factories
Dinoseb	0.007	Reproductive difficulties	Runoff from herbicide used on soybeans and vegetables
Dioxin (2,3,7,8-TCDD)	0.0000003	Reproductive difficulties, increased risk of cancer	Emissions from waste incineration and other combustion, discharge from chemical factories
Diquat	0.02	Cataracts	Runoff from herbicide use
Endothall	0.1	Gastrointestinal tract	Runoff from herbicide use
Endrin	0.002	Liver	Residue of banned insecticide
Ethylbenzene	0.7	Liver, kidneys	Discharge from petroleum refineries
Ethylene dibromide	0.00005	Liver, stomach, reproductive system, kidneys; increased risk of cancer	Discharge from petroleum refineries
Glyphosate	0.7	Kidney problems, reproductive difficulties	Runoff from herbicide use
Heptachlor	0.0004	Liver damage, increased risk of cancer	Residue of banned termiticide
Heptachlor epoxide	0.0002	Liver damage, increased risk of cancer	Breakdown of heptachlor
Hexachlorobenzene	0.001	Liver, kidneys, reproductive system; increased risk of cancer	Discharge from metal refineries and agricultural chemical factories
Hexachlorocyclopentadiene	0.05	Kidneys, stomach	Discharge from chemical factories
Lindane	0.0002	Liver, kidneys	Runoff/leaching from insecticide used on cattle, lumber, gardens
Methoxychlor	0.04	Reproductive difficulties	Runoff/leaching from insecticide used on fruits, vegetables, alfalfa, livestock
Oxamyl (Vydate)	0.2	Nervous system	Runoff/leaching from insecticide used on apples, potatoes, and tomatoes
Polychlorinated biphenyls (PCBs)	0.0005	Skin, thymus gland, immune system, reproductive, and nervous systems; increased risk of cancer	Runoff from landfills, discharge of waste chemicals

*(continues)*

**ORGANIC CHEMICALS** *(continued)*

Category	Maximum Amount (parts per million)	Body Part Affected/Disease	Sources
Polychlorinated biphenyls (PCBs)	0.0005	Skin, thymus gland, immune system, reproductive, and nervous systems; increased risk of cancer	Runoff from landfills, discharge of waste chemicals
Pentachlorophenol	0.001	Liver, kidneys; increased cancer risk	Discharge from wood-preserving factories
Picloram	0.5	Liver	Herbicide runoff
Simazine	0.004	Blood	Herbicide runoff
Styrene	0.1	Liver, kidneys, circulatory system	Discharge from rubber and plastic factories
Tetrachloroethylene	0.005	Liver, increased risk of cancer	Discharge from factories and dry cleaners
Toluene	1	Nervous system, kidney, or liver problems	Discharge from petroleum factories
Toxaphene	0.003	Kidney, liver, thyroid; increased risk of cancer	Runoff/leaching from insecticide used on cotton and cattle
2,4,5-TP (Silvex)	0.05	Liver	Residue of banned herbicide
1,2,4-Trichlorobenzene	0.07	Adrenal glands	Discharge from textile finishing factories
1,1,1-Trichloroethane	0.20	Liver, nervous system, circulatory problems	Discharge from metal degreasing sites and other factories
1,1,2-Trichloroethane	0.003	Liver, kidneys, immune system	Discharge from industrial chemical factories
Trichloroethylene	0.005	Liver problems, increased risk of cancer	Discharge from metal degreasing sites and other factories
Vinyl chloride	0.002	Increased risk of cancer	Leaching from PVC pipes, discharge from plastic factories
Xylenes (total)	10	Nervous system	Discharge from petroleum factories, discharge from chemical factories

# APPENDIX VIII

## CURRENT NATIONAL AMBIENT AIR QUALITY STANDARDS (NAAQS) FOR ALL CONTROLLED POLLUTANTS

ORGANIC CHEMICALS			
Pollutant	Primary Standards	Averaging Times	Secondary Standards
Carbon Monoxide	9 ppm (10 mg/m <sup>3</sup> )	8 hour <sup>a</sup>	None
	35 ppm (40 mg/m <sup>3</sup> )	1 hour <sup>a</sup>	None
Lead	1.5 mcg/m <sup>3</sup>	Quarterly Average	Same as Primary
Nitrogen Dioxide	0.053 ppm (100 mcg/m <sup>3</sup> )	Annual (Arithmetic Mean)	Same as Primary
Particulate Matter (PM <sup>10</sup> )	50 mcg/m <sup>3</sup>	Annual <sup>b</sup> (Arithmetic Mean)	Same as Primary
	150 mcg/m <sup>3</sup>	24 hour <sup>a</sup>	Same as Primary
Particulate Matter (PM <sup>2.5</sup> )	15.0 mcg/m <sup>3</sup>	Annual <sup>c</sup> (Arithmetic Mean)	Same as Primary
	65 mcg/m <sup>3</sup>	24 hour <sup>d</sup>	Same as Primary
Ozone	0.08 ppm	8 hour <sup>e</sup>	Same as Primary
	0.12 ppm	1 hour <sup>f</sup> (Applies only in limited areas)	Same as Primary
Sulfur Oxides	0.03 ppm	Annual (Arithmetic Mean)	—
	0.14 ppm	24 hour <sup>a</sup>	—
	—	3 hour <sup>a</sup>	0.5 ppm (1300 mcg/m <sup>3</sup> )

Notes:

<sup>a</sup> Not to be exceeded more than once per year.

<sup>b</sup> To attain this standard, the three-year average of the weighted annual mean PM<sub>10</sub> concentration at each monitor within an area must not exceed 50 mcg/m<sup>3</sup>.

<sup>c</sup> To attain this standard, the three-year average of the weighted annual mean PM<sub>2.5</sub> concentrations from single or multiple community-oriented monitors must not exceed 15.0 mcg/m<sup>3</sup>.

<sup>d</sup> To attain this standard, the three-year average of the 98th percentile of 24-hour concentrations at each population-oriented monitor within an area must not exceed 65 mcg/m<sup>3</sup>.

<sup>e</sup> To attain this standard, the three-year average of the fourth-highest daily maximal eight-hour average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.

<sup>f</sup> (a) The standard is attained when the expected number of days per calendar year with maximal hourly average concentrations above 0.12 ppm is less than one day. (b) As of June 15, 2005, EPA revoked the one-hour ozone standard in all areas except the 14 eight-hour ozone nonattainment Early Action Compact (EAC) areas.

# APPENDIX IX

## NATIONAL INSTITUTE OF OCCUPATIONAL SAFETY AND HEALTH (NIOSH) LIST OF IMMEDIATELY DANGEROUS TO LIFE AND HEALTH (IDLH) VALUES FOR CONTROLLED CHEMICALS

Substance	IDLH Value
Acetone	2,500 ppm
Acrolein	2 ppm
Aldrin	25 mg/m <sup>3</sup>
Allyl alcohol	20 ppm
Ammonia	300 ppm
Antimony compounds (as Sb)	50 mg Sb/m <sup>3</sup>
Arsenic (inorganic compounds, as As)	5 mg As/m <sup>3</sup>
Barium (soluble compounds, as Ba)	50 mg Ba/m <sup>3</sup>
Benzene	500 ppm
Beryllium compounds (as Be)	4 mg/m <sup>3</sup>
Bromine	3 ppm
1,3-Butadiene	2,000 ppm
tert-Butyl chromate	15 mg Cr(VI)/m <sup>3</sup>
Cadmium dust (as Cd)	9 mg Cd/m <sup>3</sup>
Cadmium fume (as Cd)	9 mg Cd/m <sup>3</sup>
Calcium arsenate (as As)	5 mg As/m <sup>3</sup>
Carbaryl	100 mg/m <sup>3</sup>
Carbon black	1,750 mg/m <sup>3</sup>
Carbon dioxide	40,000 ppm
Carbon monoxide	1,200 ppm
Carbon tetrachloride	200 ppm
Chlordane	100 mg/m <sup>3</sup>
Chlorobenzene	1,000 ppm
Chromic acid and chromates	15 mg Cr(VI)/m <sup>3</sup>
Chromium (II) compounds [as Cr(II)]	250 mg Cr(II)/m <sup>3</sup>
Chromium (III) compounds [as Cr(III)]	25 mg Cr(III)/m <sup>3</sup>

Substance	IDLH Value
Chromium metal (as Cr)	250 mg Cr/m <sup>3</sup>
Coal tar pitch volatiles	80 mg/m <sup>3</sup>
Cobalt metal, dust and fume (as Co)	20 mg Co/m <sup>3</sup>
Copper, dusts and mists (as Cu)	100 mg Cu/m <sup>3</sup>
Copper fume (as Cu)	100 mg Cu/m <sup>3</sup>
Cresol (o, m, p isomers)	250 ppm
Cyanides (as CN)	25 mg/m <sup>3</sup>
DDT	500 mg/m <sup>3</sup>
Dibutyl phthalate	4,000 mg/m <sup>3</sup>
o-Dichlorobenzene	200 ppm
p-Dichlorobenzene	150 ppm
1,1-Dichloroethane	3,000 ppm
1,2-Dichloroethylene	1,000 ppm
Dieldrin	50 mg/m <sup>3</sup>
Dimethylphthalate	2,000 mg/m <sup>3</sup>
Dinitroocresol	5 mg/m <sup>3</sup>
Dinitrotoluene	50 mg/m <sup>3</sup>
Di sec-octyl phthalate	5,000 mg/m <sup>3</sup>
Endrin	2 mg/m <sup>3</sup>
Ethyl benzene	800 ppm
Formaldehyde	20 ppm
Heptachlor	35 mg/m <sup>3</sup>
Hexachloroethane	300 ppm
Hexachloronaphthalene	2 mg/m <sup>3</sup>
Hydrazine	50 ppm
Hydrogen chloride	50 ppm
Hydrogen cyanide	50 ppm
Hydrogen selenide (as Se)	1 ppm
Hydrogen sulfide	100 ppm
Lead compounds (as Pb)	100 mg Pb/m <sup>3</sup>
Lindane	50 mg/m <sup>3</sup>
Lithium hydride	0.5 mg/m <sup>3</sup>
Mercury compounds [except (organo) alkyls, as Hg]	10 mg Hg/m <sup>3</sup>
Mercury (organo) alkyl compounds(as Hg)	2 mg Hg/m <sup>3</sup>
Methoxychlor	5,000 mg/m <sup>3</sup>

Substance	IDLH Value
Methyl chloride	2,000 ppm
Methylene chloride	2,300 ppm
Methyl isocyanate	3 ppm
Methyl styrene	700 ppm
Naphtha (coal tar)	1,000 ppm
Naphthalene	250 ppm
Nickel carbonyl (as Ni)	2 ppm
Nickel metal and other compounds (as Ni)	10 mg Ni/m <sup>3</sup>
Nicotine	5 mg/m <sup>3</sup>
Nitrogen dioxide	20 ppm
Oil mist (mineral)	2,500 mg/m <sup>3</sup>
Ozone	5 ppm
Pentachloronaphthalene	Unknown
Pentachlorophenol	2.5 mg/m <sup>3</sup>
Phenol	250 ppm
Phosgene	2 ppm
Phosphorus (yellow)	5 mg/m <sup>3</sup>
Phosphorus pentachloride	70 mg/m <sup>3</sup>
Phosphorus pentasulfide	250 mg/m <sup>3</sup>
Phosphorus trichloride	25 ppm
Phthalic anhydride	60 mg/m <sup>3</sup>
Selenium compounds (as Se)	1 mg Se/m <sup>3</sup>
Selenium hexafluoride	2 ppm
Styrene	700 ppm
Sulfur dioxide	100 ppm
1,1,2,2-Tetrachloroethane	100 ppm
Tetrachloroethylene	150 ppm
Tetrachloronaphthalene	Unknown
Tetraethyl lead (as Pb)	40 mg Pb/m <sup>3</sup>
Tetrahydrofuran	2,000 ppm
Tetramethyl lead (as Pb)	40 mg Pb/m <sup>3</sup>
Toluene	500 ppm
Toluene 2,4-diisocyanate	2.5 ppm
Trichloroethylene	1,000 ppm
Trichloronaphthalene	Unknown

Substance	IDLH Value
Uranium (insoluble compounds, as U)	10 mg U/m <sup>3</sup>
Uranium (soluble compounds, as U)	10 mg U/m <sup>3</sup>
Xylene (o, m, p isomers)	900 ppm
Zinc chloride fume	50 mg/m <sup>3</sup>
Zinc oxide	500 mg/m <sup>3</sup>

# APPENDIX X

## U.S. EPA NATIONAL AIR QUALITY INDEX

AQI Value	Air Quality	General Health Effects	Recommended Actions
0–50	Good	None	
51–100	Moderate	There may be moderate health concern for a very small number of individuals. People unusually sensitive to ozone may experience respiratory symptoms	When O <sub>3</sub> AQI values are in this range, unusually sensitive people should consider limiting prolonged outdoor exposure
101–150	Unhealthy for sensitive groups	Mild aggravation of symptoms in susceptible persons.	Active people with respiratory or heart disease should limit prolonged outdoor exertion.
151–200	Unhealthy	Aggravation of symptoms in susceptible persons, with irritation symptoms in the healthy population.	Active children and adults with respiratory or heart disease should avoid extended outdoor activities; everyone else, especially children, should limit prolonged outdoor activity.
201–300	Very unhealthy	Significant aggravation of symptoms and decreased exercise tolerance in persons with heart or lung disease, with widespread symptoms in the healthy population.	Active children and adults with existing heart or lung disease should avoid outdoor activities and exertion. Everyone else, especially children, should limit outdoor exertion.
301–500	Hazardous	Significant aggravation of symptoms. Premature onset of certain diseases. Premature death may occur in ill or elderly people. Healthy people may experience a decrease in exercise tolerance.	Everyone should avoid all outdoor exertion and minimize physical outdoor activities. Elderly adults and persons with existing heart or lung disease should stay indoors.

Note: Used in air quality ratings in daily weather reports

# APPENDIX XI

## CHEMICALS ANALYZED AT SUPERFUND SITES

• Acetone	• Lead
• Aldrin/Dieldrin	• Mercury
• Arsenic	• Methylene Chloride
• Barium	• Naphthalene
• Benzene	• Nickel
• 2-Butanone	• Pentachlorophenol
• Cadmium	• Polychlorinated Biphenyls (PCBs)
• Carbon Tetrachloride	• Polycyclic Aromatic Hydrocarbons (PAHs)
• Chlordane	• Tetrachloroethylene
• Chloroform	• Toluene
• Chromium	• Trichloroethylene
• Cyanide	• Vinyl Chloride
• DDT, DDE, DDD	• Xylene: pending
• 1,1-Dichloroethene	• Zinc
• 1,2-Dichloroethane	

# APPENDIX XII

## U.S. NATIONAL PRIORITIES LIST (NPL OR SUPERFUND) SITES (FIGURES REPORTED AS OF NOVEMBER 29, 2010)

No.	Site Name	State/Location	Listing Date
1	Alabama Army Ammunition Plant	Alabama	1987
2	American Brass Inc.	Alabama	1999
3	Anniston Army Depot (Southeast Industrial Area)	Alabama	1989
4	Ciba-Geigy Corp. (Mcintosh Plant)	Alabama	1984
5	Interstate Lead Co. (Ilco)	Alabama	1986
6	Olin Corp. (Mcintosh Plant)	Alabama	1984
7	Perdido Groundwater Contamination	Alabama	1983
8	Redwing Carriers, Inc. (Saraland)	Alabama	1990
9	Stauffer Chemical Co. (Cold Creek Plant)	Alabama	1984
10	Stauffer Chemical Co. (Lemoyne Plant)	Alabama	1984
11	T. H. Agriculture & Nutrition Co. (Montgomery Plant)	Alabama	1990
12	Triana/Tennessee River	Alabama	1983
13	U.S. Army/NASA Redstone Arsenal	Alabama	1994
1	Adak Naval Air Station	Alaska	1994
2	Eielson Air Force Base	Alaska	1989
3	Elmendorf Air Force Base	Alaska	1990
4	Fort Richardson (U.S. Army)	Alaska	1994
5	Fort Wainwright	Alaska	1990
6	Salt Chuck Mine	Alaska	2010
1	Apache Powder Co.	Arizona	1990
2	Hassayampa Landfill	Arizona	1987
3	Indian Bend Wash Area	Arizona	1983
4	Iron King Mine–Humboldt Smelter	Arizona	2008
5	Motorola, Inc. (52nd Street Plant)	Arizona	1989
6	Phoenix-Goodyear Airport Area	Arizona	1983
7	Tucson International Airport Area	Arizona	1983

No.	Site Name	State/Location	Listing Date
8	Williams Air Force Base	Arizona	1989
9	Yuma Marine Corps Air Station	Arizona	1990
1	Arkwood, Inc.	Arkansas	1989
2	Midland Products	Arkansas	1986
3	Mid-South Wood Products	Arkansas	1983
4	Monroe Auto Equipment Co. (Paragould Pit)	Arkansas	1990
5	Mountain Pine Pressure Treating	Arkansas	1999
6	Ouachita Nevada Wood Treater	Arkansas	2000
7	Popile, Inc.	Arkansas	1992
8	Vertac, Inc.	Arkansas	1983
1	Advanced Micro Devices, Inc.	California	1986
2	Advanced Micro Devices, Inc. (Building 915)	California	1990
3	Aerojet General Corp.	California	1983
4	Alameda Naval Air Station	California	1999
5	Alark Hard Chrome	California	2000
6	AMCO Chemical	California	2003
7	Applied Materials	California	1987
8	Atlas Asbestos Mine	California	1984
9	Barstow Marine Corps Logistics Base	California	1989
10	Beckman Instruments (Porterville Plant)	California	1986
11	BF Goodrich	California	2009
12	Brown & Bryant, Inc. (Arvin Plant)	California	1989
13	Camp Pendleton Marine Corps Base	California	1989
14	Casmalia Resources	California	2001
15	Castle Air Force Base (six areas)	California	1987
16	Coast Wood Preserving	California	1983
17	Concord Naval Weapons Station	California	1994
18	Cooper Drum Co.	California	2001
19	Crazy Horse Sanitary Landfill	California	1990
20	CTS Printex, Inc.	California	1990
21	Del Amo	California	2002
22	Edwards Air Force Base	California	1990
23	El Toro Marine Corps Air Station	California	1990
24	Fairchild Semiconductor Corp. (Mountain View Plant)	California	1991

No.	Site Name	State/Location	Listing Date
25	Fairchild Semiconductor Corp. (South San Jose Plant)	California	1989
26	Fort Ord	California	1990
27	Fresno Municipal Sanitary Landfill	California	1989
28	Frontier Fertilizer	California	1994
29	George Air Force Base	California	1990
30	Halaco Engineering Co	California	2007
31	Hewlett-Packard (620–640 Page	California	1990
32	Industrial Waste Processing	California	1990
33	Intel Corp. (Mountain View Plant)	California	1986
34	Intel Corp. (Santa Clara III )	California	1986
35	Intel Magnetics	California	06/10/1986
36	Intersil Inc./Siemens Components	California	1990
37	Iron Mountain Mine	California	1983
38	J. H. Baxter & Co.	California	1989
39	Jasco Chemical Corp.	California	1989
40	Jet Propulsion Laboratory (NASA)	California	1992
41	Klau/Buena Vista Mine	California	2006
42	Koppers Co., Inc. (Oroville Plant)	California	1984
43	Lava Cap Mine	California	1999
44	Lawrence Livermore National Lab (Site 300) (U.S. DOE)	California	1990
45	Lawrence Livermore National Lab, Main Site (U.S. DOE)	California	1987
46	LEHR/Old Campus Landfill (U.S. DOE)	California	1994
47	Leviathan Mine	California	2000
48	Lorentz Barrel & Drum Co.	California	1989
49	March Air Force Base	California	1989
50	Mather Air Force Base (Ac&W Disposal Site)	California	1987
51	McClellan Air Force Base (Groundwater Contamination)	California	1987
52	McColl	California	1983
53	McCormick & Baxter Creosoting Co.	California	1992
54	MGM Brakes	California	1983
55	Modesto Groundwater Contamination	California	1989
56	Moffett Naval Air Station	California	1987
57	Monolithic Memories	California	1987
58	Montrose Chemical Corp.	California	1989
59	National Semiconductor Corp.	California	1987

No.	Site Name	State/Location	Listing Date
59	National Semiconductor Corp.	California	1987
60	Newmark Groundwater Contamination	California	1989
61	Norton Air Force Base (Landfill #2)	California	1987
62	Omega Chemical Corporation	California	1999
63	Operating Industries, Inc., Landfill	California	1986
64	Pacific Coast Pipe Lines	California	1989
65	Pemaco Maywood	California	1999
66	Purity Oil Sales, Inc.	California	1983
67	Raytheon Corp.	California	1986
68	Riverbank Army Ammunition Plant	California	1990
69	Sacramento Army Depot	California	1987
70	San Fernando Valley (Area 1)	California	1986
71	San Fernando Valley (Area 2)	California	1986
72	San Fernando Valley (Area 4)	California	1986
73	San Gabriel Valley (Area 1)	California	1984
74	San Gabriel Valley (Area 2)	California	1984
75	San Gabriel Valley (Area 3)	California	1984
76	San Gabriel Valley (Area 4)	California	1984
77	Selma Treating Co.	California	1983
78	Sharpe Army Depot	California	1987
79	Sola Optical USA, Inc.	California	1990
80	South Bay Asbestos Area	California	1986
81	Spectra-Physics, Inc.	California	1991
82	Stringfellow	California	1983
83	Sulphur Bank Mercury Mine	California	1990
84	Synertek, Inc. (Building 1)	California	1989
85	Teledyne Semiconductor	California	1987
86	Tracy Defense Depot (U.S. Army)	California	1990
87	Travis Air Force Base	California	1989
88	Treasure Island Naval Station—Hunters Point Annex	California	1989
89	TRW Microwave, Inc. (Building 825)	California	1990
90	United Heckathorn Co.	California	1990
91	Valley Wood Preserving, Inc.	California	1989
92	Waste Disposal, Inc.	California	1987
93	Watkins-Johnson Co. (Stewart Division Plant)	California	1990

No.	Site Name	State/Location	Listing Date
94	Westinghouse Electric Corp. (Sunnyvale Plant)	California	1986
1	Air Force Plant PJKS	Colorado	1989
2	Broderick Wood Products	Colorado	1984
3	California Gulch	Colorado	1983
4	Captain Jack Mill	Colorado	2003
5	Central City, Clear Creek	Colorado	1983
6	Chemical Sales Co.	Colorado	1990
7	Denver Radium Site	Colorado	1983
8	Eagle Mine	Colorado	1986
9	Lincoln Park	Colorado	1984
10	Lowry Landfill	Colorado	1984
11	Marshall Landfill	Colorado	1983
12	Rocky Flats Plant (U.S. DOE)	Colorado	1989
13	Rocky Mountain Arsenal (U.S. Army)	Colorado	1987
14	Standard Mine	Colorado	2005
15	Summitville Mine	Colorado	1994
16	Uravan Uranium Project (Union Carbide Corp.)	Colorado	1986
17	Vasquez Boulevard and I-70	Colorado	1999
1	Barkhamsted–New Hartford Landfill	Connecticut	1989
2	Beacon Heights Landfill	Connecticut	1983
3	Durham Meadows	Connecticut	1989
4	Gallup's Quarry	Connecticut	1989
5	Kellogg-Deering Well Field	Connecticut	1984
6	Laurel Park, Inc.	Connecticut	1983
7	Linemaster Switch Corp.	Connecticut	1990
8	New London Submarine Base	Connecticut	1990
9	Old Southington Landfill	Connecticut	1984
10	Precision Plating Corp.	Connecticut	1989
11	Raymark Industries, Inc.	Connecticut	1995
12	Scovill Industrial Landfill	Connecticut	2000
13	Solvents Recovery Service of New England	Connecticut	1983
14	Yaworski Waste Lagoon	Connecticut	1983
1	Army Creek Landfill	Delaware	1983

No.	Site Name	State/Location	Listing Date
2	Chem-Solv, Inc.	Delaware	1990
3	Coker's Sanitation Service Landfills	Delaware	1987
4	Delaware City PVC Plant	Delaware	1983
5	Delaware Sand & Gravel Landfill	Delaware	1983
6	Dover Air Force Base	Delaware	1989
7	Dover Gas Light Co.	Delaware	1989
8	E. I. Du Pont de Nemours & Co., Inc. (Newport Pigment Plant Landfill)	Delaware	1990
9	Halby Chemical Co.	Delaware	1986
10	Harvey & Knott Drum, Inc.	Delaware	1983
11	Koppers Co., Inc. (Newport Plant)	Delaware	1990
12	NCR Corp. (Millsboro Plant)	Delaware	1987
13	Standard Chlorine of Delaware, Inc.	Delaware	1987
14	Tybouts Corner Landfill	Delaware	1983
1	Washington Navy Yard	District of Columbia	1998
1	Agrico Chemical Co.	Florida	1989
2	Airco Plating Co.	Florida	1990
3	Alaric Area GW Plume	Florida	2000
4	American Creosote Works, Inc. (Pensacola Plant)	Florida	1983
5	Anodyne, Inc.	Florida	1990
6	B&B Chemical Co., Inc.	Florida	1990
7	Cabot/Koppers	Florida	1984
8	Chevron Chemical Co. (Ortho Division)	Florida	1994
9	City Industries, Inc.	Florida	1989
10	Coleman-Evans Wood Preserving Co.	Florida	1983
11	Escambia Wood—Pensacola	Florida	1994
12	Flash Cleaners	Florida	2008
13	Florida Petroleum Reprocessors	Florida	1998
14	Florida Steel Corp.	Florida	1983
15	General Dynamics Longwood	Florida	2010
16	Harris Corp. (Palm Bay Plant)	Florida	1987
17	Helena Chemical Co. (Tampa Plant)	Florida	1992
18	Hipps Road Landfill	Florida	1984
19	Hollingsworth Solderless Terminal	Florida	1983

No.	Site Name	State/Location	Listing Date
20	Homestead Air Force Base	Florida	1990
21	Jacksonville Naval Air Station	Florida	1989
22	J J Seifert Machine	Florida	2010
23	Landia Chemical Company	Florida	2000
24	Kerr-McGee Chemical Corp.—Jackson	Florida	2010
25	Madison County Sanitary Landfill	Florida	1990
26	Miami Drum Services	Florida	1983
27	MRI Corp (Tampa)	Florida	1986
28	Peak Oil Co./Bay Drum Co.	Florida	1986
29	Pensacola Naval Air Station	Florida	1989
30	Pepper Steel & Alloys, Inc.	Florida	1984
31	Petroleum Products Corp.	Florida	1987
32	Pickettville Road Landfill	Florida	1983
33	Piper Aircraft Corp./Vero Beach Water & Sewer Department	Florida	1990
34	Raleigh Street Dump	Florida	2009
35	Reeves Southeastern Galvanizing Corp.	Florida	1983
36	Sanford Dry Cleaners	Florida	2010
37	Sapp Battery Salvage	Florida	1983
38	Sherwood Medical Industries	Florida	1983
39	Solitron Microwave	Florida	1998
40	Southern Solvents, Inc.	Florida	2000
41	Stauffer Chemical Co (Tampa)	Florida	1996
42	Stauffer Chemical Co. (Tarpon Springs)	Florida	1994
43	Sydney Mine Sludge Ponds	Florida	1989
44	Taylor Road Landfill	Florida	1983
45	Tower Chemical Co.	Florida	1983
46	Trans Circuits, Inc.	Florida	2000
47	Tyndall Air Force Base	Florida	1997
48	United Metals, Inc.	Florida	2003
49	USN Air Station Cecil Field	Florida	1989
50	Whitehouse Oil Pits	Florida	1983
51	Whiting Field Naval Air Station	Florida	1994
52	Wingate Road Municipal Incinerator Dump	Florida	1989
53	Zellwood Groundwater Contamination	Florida	1983
1	Alternate Energy Resources	Georgia	2006

No.	Site Name	State/Location	Listing Date
2	Brunswick Wood Preserving	Georgia	1997
3	Camilla Wood Preserving Company	Georgia	1998
4	Diamond Shamrock Corp. Landfill	Georgia	1990
5	Firestone Tire & Rubber Co. (Albany Plant)	Georgia	1989
6	Hercules 009 Landfill	Georgia	1984
7	LCP Chemicals Georgia	Georgia	1996
8	Marine Corps Logistics Base	Georgia	1989
9	Marzone Inc./Chevron Chemical Co.	Georgia	1989
10	Mathis Brothers Landfill (South Marble Top Road)	Georgia	1989
11	Peach Orchard Road Pce Ground Water Plume	Georgia	2005
12	Robins Air Force Base (Landfill #4/Sludge Lagoon)	Georgia	1987
13	T.H. Agriculture & Nutrition Co. (Albany Plant)	Georgia	1989
14	Woolfolk Chemical Works, Inc.	Georgia	1990
1	Andersen Air Force Base	Guam	1992
2	Ordot Landfill	Guam	1983
1	Del Monte Corp. (Oahu Plantation)	Hawaii	1994
2	Naval Computer and Telecommunications Area Master Station Eastern Pacific	Hawaii	1994
3	Pearl Harbor Naval Complex	Hawaii	1992
1	Bunker Hill Mining & Metallurgical Complex	Idaho	1983
2	Eastern Michaud Flats Contamination	Idaho	1990
3	Idaho National Engineering Laboratory (U.S. DOE)	Idaho	1989
4	Kerr-McGee Chemical Corp. (Soda Springs Plant)	Idaho	1989
5	Monsanto Chemical Co. (Soda Springs Plant)	Idaho	1990
6	Mountain Home Air Force Base	Idaho	1990
1	A & F Material Reclaiming, Inc.	Illinois	1983
2	Acme Solvent Reclaiming, Inc. (Morristown Plant)	Illinois	1983
3	Adams County Quincy Landfills 2 & 3	Illinois	1990
4	Amoco Chemicals (Joliet Landfill)	Illinois	1990
5	ASARCO Taylor Springs	Illinois	2006
6	Beloit Corp.	Illinois	1990
7	Belvidere Municipal Landfill	Illinois	1983

No.	Site Name	State/Location	Listing Date
8	Byron Salvage Yard	Illinois	1983
9	Central Illinois Public Service Co.	Illinois	1990
10	Cross Brothers Pail Recycling (Pembroke)	Illinois	1983
11	Depue/New Jersey Zinc/Mobil Chemical Corp.	Illinois	1999
12	Dupage County Landfill/Blackwell Forest Preserve	Illinois	1990
13	Eagle Zinc Co. Div. of T. L. Diamond	Illinois	2007
14	Galesburg/Koppers Co.	Illinois	1983
15	H.O.D. Landfill	Illinois	1990
16	Hegeler Zinc	Illinois	2005
17	Indian Refinery—Texaco Lawrenceville	Illinois	2000
18	Interstate Pollution Control, Inc.	Illinois	1989
19	Jennison-Wright Corporation	Illinois	1996
20	Johns-Manville Corp.	Illinois	1983
21	Joliet Army Ammunition Plant (Load-Assembly-Packing Area)	Illinois	1989
22	Joliet Army Ammunition Plant (Manufacturing Area)	Illinois	1987
23	Kerr-McGee (Kress Creek/West Branch of Dupage River)	Illinois	1991
24	Kerr-McGee (Residential Areas)	Illinois	1990
25	Kerr-McGee (Sewage Treatment Plant)	Illinois	1990
26	Lake Calumet Cluster	Illinois	2010
27	Lasalle Electric Utilities	Illinois	1983
28	Lenz Oil Service, Inc.	Illinois	1989
29	Matthiessen and Hegeler Zinc Company	Illinois	2003
30	MIG/Dewane Landfill	Illinois	1990
31	NL Industries/Taracorp Lead Smelter	Illinois	1986
32	Ottawa Radiation Areas	Illinois	1992
33	Outboard Marine Corp.	Illinois	1983
34	Pagel's Pit	Illinois	1986
35	Parsons Casket Hardware Co.	Illinois	1987
36	Sangamo Electric Dump/Crab Orchard National Wildlife Refuge (U.S. DOI)	Illinois	1987
37	Savanna Army Depot Activity	Illinois	1989
38	Southeast Rockford Groundwater Contamination	Illinois	1989
39	Tri-County Landfill Co./Waste Management of Illinois, Inc.	Illinois	1989
40	Velsicol Chemical Corp. (Marshall Plant)	Illinois	1983
41	Wauconda Sand & Gravel	Illinois	1983
42	Woodstock Municipal Landfill	Illinois	1989
43	Yeoman Creek Landfill	Illinois	1989

No.	Site Name	State/Location	Listing Date
1	American Chemical Service, Inc.	Indiana	1984
2	Bennett Stone Quarry	Indiana	1984
3	Cam-Or, Inc.	Indiana	1998
4	Columbus Old Municipal Landfill #1	Indiana	1986
5	Conrail Rail Yard (Elkhart)	Indiana	1990
6	Continental Steel Corp.	Indiana	1989
7	Douglass Road/Uniroyal, Inc., Landfill	Indiana	1989
8	Elm Street Groundwater Contamination	Indiana	2007
9	Envirochem Corp.	Indiana	1983
10	Fisher-Calo	Indiana	1983
11	Fort Wayne Reduction Dump	Indiana	1986
12	Galen Myers Dump/Drum Salvage	Indiana	1989
13	Himco Dump	Indiana	1990
14	Jacobsville Neighborhood Soil Contamination	Indiana	2004
15	Lake Sandy Jo (M&M Landfill)	Indiana	1983
16	Lakeland Disposal Service, Inc.	Indiana	1989
17	Lemon Lane Landfill	Indiana	1983
18	Lusher Street Groundwater Contamination	Indiana	2008
19	Main Street Well Field	Indiana	1983
20	Marion (Bragg) Dump	Indiana	1983
21	MIDCO I	Indiana	1983
22	MIDCO II	Indiana	1986
23	Neal's Landfill (Bloomington)	Indiana	1983
24	Ninth Avenue Dump	Indiana	1983
25	Northside Sanitary Landfill, Inc.	Indiana	1984
26	Prestolite Battery Division	Indiana	1989
27	Reilly Tar & Chemical Corp. (Indianapolis Plant)	Indiana	1984
28	Seymour Recycling Corp.	Indiana	1983
29	Tippecanoe Sanitary Landfill, Inc.	Indiana	1990
30	U.S. Smelter and Lead Refinery, Inc.	Indiana	2009
31	Wayne Waste Oil	Indiana	1983
1	Des Moines TCE	Iowa	1983
2	Electro-Coatings, Inc.	Iowa	1989
3	Fairfield Coal Gasification Plant	Iowa	1990
4	Iowa Army Ammunition Plant	Iowa	1990

No.	Site Name	State/Location	Listing Date
5	Lawrence Todtz Farm	Iowa	1986
6	Mason City Coal Gasification Plant	Iowa	1994
7	Midwest Manufacturing/North Farm	Iowa	1986
8	Peoples Natural Gas Co.	Iowa	1990
9	Railroad Avenue Groundwater Contamination Site	Iowa	2002
10	Shaw Avenue Dump	Iowa	1987
11	Vogel Paint & Wax Co.	Iowa	1986
1	57th and North Broadway Streets Site	Kansas	1992
2	Ace Services	Kansas	1995
3	Chemical Commodities, Inc.	Kansas	1994
4	Cherokee County	Kansas	1983
5	Doepke Disposal (Holliday)	Kansas	1983
6	Fort Riley	Kansas	1990
7	Obee Road	Kansas	1987
8	Pester Refinery Co.	Kansas	1989
9	Plating, Inc.	Kansas	2008
10	Strother Field Industrial Park	Kansas	1986
11	Wright Ground Water Contamination	Kansas	1996
1	Airco	Kentucky	1984
2	B. F. Goodrich	Kentucky	1983
3	Brantley Landfill	Kentucky	1990
4	Caldwell Lace Leather Co., Inc.	Kentucky	1990
5	Distler Brickyard	Kentucky	1983
6	Distler Farm	Kentucky	1983
7	Fort Hartford Coal Co. Stone Quarry	Kentucky	1990
8	Green River Disposal, Inc.	Kentucky	1990
9	Maxey Flats Nuclear Disposal	Kentucky	1986
10	National Electric Coil Co./Cooper Industries	Kentucky	1992
11	National Southwire Aluminum Co.	Kentucky	1994
12	Paducah Gaseous Diffusion Plant (U.S. DOE)	Kentucky	1994
13	Smith's Farm	Kentucky	1986
14	Tri-City Disposal Co.	Kentucky	1989
1	Agriculture Street Landfill	Louisiana	1994

No.	Site Name	State/Location	Listing Date
2	American Creosote Works, Inc. (Winnfield Plant)	Louisiana	1992
3	Bayou Bonfouca	Louisiana	1983

## TOP 25 OIL SPILLS IN THE WORLD

Rank	Date	Incident/Location	Millions of Gallons (Liters)
1	January 26, 1991	Terminals, tankers, eight sources total Sea Island installations; Kuwait; Persian Gulf; Saudi Arabia	240.0 (90 7.2)
2	April 20, 2010	Exploratory well <i>Deepwater Horizon</i> ; 40 miles (66 km) off the SE coast of Louisiana, United States; Gulf of Mexico	204 (775.2)
3	June 3, 1979	Exploratory well Ixtoc I; Mexico; Gulf of Mexico, Bahía de Campeche; 48 miles (80 km) NW of Ciudad del Carmen, Campeche	140.0 (529.2)
4	February 4, 1983	Platform #3 well (Nowruz) Iran; Persian Gulf, Nowruz Field	80.0 (302.4)
5	August 6, 1983	Tanker <i>Castillo de Bellver</i> ; South Africa; Atlantic Ocean, 38.4 miles (64 km) off Table Bay	78.5 (296.7)
6	March 16, 1978	Tanker <i>Amoco Cadiz</i> ; France; Atlantic Ocean, off Porsall, Brittany	68.7 (259.7)
7	November 10, 1988	Tanker <i>Odyssey</i> ; Canada; North Atlantic Ocean, 705 miles (1,175 km) NE of St. John's, Newfoundland	43.1 (162.9)
8	July 19, 1979	Tanker <i>Atlantic Empress</i> ; Trinidad and Tobago; Caribbean Sea, 19.2 miles (32 km) NE of Trinidad-and Tobago	42.7* (161.4)
9	April 11, 1991	Tanker <i>Haven</i> ; Italy; Mediterranean Sea, port of Genoa	42.0 (158.8)
10	August 2, 1979	Tanker <i>Atlantic Empress</i> ; 370 miles (450 km) east of Barbados	41.5* (156.9)
11	March 18, 1967	Tanker <i>Torrey Canyon</i> ; United Kingdom; Lands End	38.2 (144.4)
12	December 19, 1972	Tanker <i>Sea Star</i> ; Oman; Gulf of Oman	37.9 (143.3)
13	February 23, 1980	Tanker <i>Irenes Serenade</i> ; Greece; Mediterranean Sea, Navarino Bay	36.6 (138.3)
14	December 7, 1971	Tanker <i>Texaco Denmark</i> ; Belgium; North Sea	31.5 (119.1)
15	February 23, 1980	Tanker <i>Hawaiian Patriot</i> ; United States; Pacific Ocean, 356 miles (593 km) west of Kauai Island, Hawaii	31.2** (117.9)
16	November 15, 1979	Tanker <i>Independenza</i> ; Turkey, Bosphorus Strait near Istanbul	28.9 (109.2)

Rank	Date	Incident/Location	Millions of Gallons (Liters)
17	February 11, 1969	Tanker <i>Julius Schindler</i> ; Portugal; Ponta Delgada, Azores Islands	28.4 (107.3)
18	May 12, 1976	Tanker <i>Urquiola</i> ; Spain; La Coruña Harbor port	28.1 (106.2)
19	January 5, 1993	Tanker <i>Braer</i> ; United Kingdom; Garth Ness, Shetland Islands	25.0 (94.5)
20	January 29, 1975	Tanker <i>Jacob Maersk</i> ; Portugal; Porto de Leixões, Oporto	24.3 (91.8)
21	December 3, 1992	Double-bottom tanker <i>Aegean Sea</i> ; Spain; La Coruña Harbor port	21.9 (82.8)
22	December 6, 1985	Tanker <i>Nova</i> ; Iran; Persian Gulf, 84 miles (140 km) south of Kharg Island	21.4 (80.9)
23	February 15, 1996	Tanker <i>Sea Empress</i> ; United Kingdom; Mill Bay near entrance to Milford Haven Harbor port	21.3 (80.5)
24	February 27, 1971	Tanker <i>Wafra</i> ; South Africa; Atlantic Ocean	20.2 (76.4)
25	December 19, 1989	Tanker <i>Khark 5</i> ; Morocco; Atlantic Ocean, 111 miles (185 km) from Moroccan coast	20.0 (75.6)

## Notes:

\* On July 19, 1979, the *Atlantic Empress* spilled 42.7 million gallons (162.3 million L) of oil as the result of a collision with the *Aegean Captain* in the Caribbean Sea near Trinidad and Tobago. In this incident, the *Aegean Captain* spilled 4.31 million gallons (16.4 million L) of oil. On August 2, 1979, while under tow from the original spill site, the *Atlantic Empress* spilled an additional 41.5 million gallons (157.7 million L).

\*\* In this incident the vessel sank with some of its cargo still onboard after spilling an undetermined amount of oil. The spill size reported reflects the total amount of oil spilled and oil left onboard the sinking vessel. Estimates of the two accounts are not available.

Misc: There have been 55 marine oil spills exceeding 10 million gallons (33 million L) since 1960.

Source: Data from *Oil Spill Intelligence Report*, Arlington, Mass. Web site: <http://cutter.com/osir/biglist.htm>.
